In May 1976 nine samples of bottom water were collected along the central axis of the Galapagos Spreading Center^{7,8} using a newly-devised hydrographic sampling sled^{9,10} attached to the Scripps Institution of Oceanography deep-tow instrument. The location of the samples relative to the local topography is described in the accompanying paper¹⁰. Three of these samples were collected during 'hydrothermal spike' temperature excursions whose origin could not be explained by turbulent mixing within the ambient water mass. The samples were taken about 10 m above the axial fissure opening, at the same level as the CTD sensor which recorded the temperature anomalies. When the sled was recovered, samples for helium analysis were sealed in copper tubing pinch-clamp containers and returned to the laboratory for analysis on a ³He/⁴He ratio mass spectrometer as described previously^{3,5}. Radon activities were measured at sea on six of these samples, using our normal shipboard extraction and counting techniques¹¹ with the exception that the analyses were made on one, rather than twenty, litres of water.

Table 1 lists the ³He results on the three samples taken during temperature spikes (7–0, 8–3, and 8–6) and on the samples of normal or 'background' bottom water where no temperature anomalies were observed on the continuous tow record. The measurements are tabulated as percent deviations of the ³He/⁴He ratio (*R*) from the atmospheric ratio (1.40 × 10⁻⁶), that is

$$\delta(^3\text{He}) = 100 [(R/R_{\text{Atm}}) - 1]$$

The mean background water anomaly is $\delta(^3\text{He}) = 30.4\%$, in excellent agreement with values of 30.3 and 31.0% observed on the crest and at the mid-depth ³He maximum on the eastern flank of the East Pacific Rise, south and west of the present area². Relative to this background water, which is presumably the water entering the hydrothermal system, the ³He/⁴He ratio in sample 7–0 is enriched by 53% (1.99/1.30). The other two plume samples are also enriched in ³He relative to ambient background, but by much smaller amounts. The $\delta(^3\text{He})$ value of 99% measured on sample 7–0 is by far the largest value yet observed in ocean waters, and establishes for the first time a clear connection between the mantle helium in oceanic basalts and the excess ³He observed in the deep oceans, by seawater penetration and circulation in the basalts.

Radon concentrations (Table 1) are reported as 'excess radon' relative to the activity of ²²⁶Ra. The ²²⁶Ra activity was assumed to be 33 d.p.m. per 100 kg from a previous study by this laboratory¹¹ on bottom waters 29 km south-west of the present location in approximately the same depth; rough measurements made on the present small samples were in

Table 1 ^3He and ^{222}Rn measurements on hydrothermal plume and background water on the Galapagos Rift ($\sim 0^\circ 48'\text{N}$, $85^\circ 55'\text{W}$)

Tow no., bottle no.	$\delta(^3\text{He})$ (‰)	Excess ^{222}Rn (d.p.m. per 100 kg)
<i>a</i> Samples with potential-temperature spikes		
7-0*	99.3	191
8-3	35.7	80
8-6	42.6	229
<i>b</i> 'Background water'		
7-1	27.8	39
7-2	—	49
8-1	28.6	—
8-2	30.2	33
8-5	33.4	—
8-7	32.2	—
Mean	30.4 ± 2	40 ± 8

Radon precision = ± 3 d.p.m. per 100 kg (counting error); ^{226}Ra activity assumed = 33 d.p.m. per 100 kg. $^3\text{He}/^4\text{He}$ ratios are accurate to $\pm 0.7\%$ in $\delta(^3\text{He})$.

*The temperature spike for sample 7-0 is shown in Fig. 1 of ref. 10; samples 8-3 and 8-6 were collected from plumes showing smaller temperature spikes.

agreement within the larger errors. The excess radon concentrations in the three plume samples (80–229 d.p.m. per 100 kg) are clearly much greater than the background value of about forty, although they do not scale with the ^3He anomalies. Because of the short radioactive mean life (5.5 d) the ^{222}Rn enrichments in plume waters are probably due to extraction of radon from the basalts, although some contribution from sediment material trapped within the axial fissure cannot be excluded.

Fig. 1 shows the absolute ^3He and ^4He concentrations in the deep tow samples, together with atmospheric solubility values and vectors for addition of atmospheric helium to air-saturated deep water, and for addition of radiogenic ^4He and pure 'mantle helium' (basalt values^{3,4}) to background water on the Galapagos spreading centre. (The 'absolute' concentrations, based on preliminary 'peak-height' determinations for ^4He , are accurate to about 5%; more accurate isotope dilution measurements are in progress.) ^3He and ^4He enrichments in the ambient background water relative to equilibrium solubility represent the net effect of air injection¹² and addition of mantle

and radiogenic helium to deep water during its circulation. The absolute helium anomalies in sample 7-0 are very much larger: ^3He and ^4He concentrations are respectively 75% and 14% greater in this sample than in the mean Galapagos background water.

The added increment of ^3He relative to background water is $5.9 \times 10^{-14} \text{ cm}^3 \text{ STP per g}$ in sample 7-0, an amount approximately equal to the initial solubility equilibrium (Fig. 1) and thus about 0.03% of the ^3He concentration observed in the Red Sea brines. The estimated temperature of inflowing Red Sea brines is $\sim 100^\circ\text{C}$ (ref. 13); thus if the hydrothermal systems in Red Sea and Galapagos basalts are at all similar, a temperature spike of $\sim 0.03^\circ\text{C}$ is predicted for sample 7-0, in reasonable agreement with the signal observed during sampling¹⁰.

In Fig. 1 the vector from the mean background water to sample 7-0 corresponds to addition of helium with $^3\text{He}/^4\text{He} = 9.4 \times 10^{-8}$ or $R = 6.7 R_{\text{Atm}}$, significantly lower than the 'mantle helium' ratio ($R \sim 10 R_{\text{Atm}}$) observed in ocean-ridge basalts^{3,4}, which implies that about 30% of the added helium is radiogenic ^4He generated in the oceanic crust. Helium with $R = 6.7 R_{\text{Atm}}$ would be found in Pacific ridge-basalts after about 30 my of ^4He production (ref. 4), an age far too great for basalts in such close proximity to the rift axis. The holocrystalline portions of pillow basalts exchange trapped gases with seawater on a much shorter time scale than this¹⁴; thus the helium isotope ratios in basalt-seawater hydrothermal systems probably decrease continuously with time as the initial mantle helium component is progressively stripped out by the fluid phase and the radiogenic component grows in. It may therefore be possible to characterise such hydrothermal systems in time and space by detailed mapping of helium isotope ratios in plume samples.

The extreme sensitivity of helium and radon for plume detection is indicated by our estimate that sample 7-0 contained of the order of 0.03% of hydrothermal water. A sample with a 1°C temperature spike would, on this basis, contain helium with $R \sim 5.5 R_{\text{Atm}}$ and a ^{222}Rn activity of $\sim 5,000$ d.p.m. per 100 kg. Radon is of course a radiogenic isotope which is present in very high activity in marine sediments; it is therefore not a completely unambiguous tracer for seawater which has penetrated basalts. The ^3He signature, however, provided unequivocal evidence for the existence of a hydrothermal basalt-seawater system in the axial region of the Galapagos Rift.

We thank Dr F. N. Spiess for his strong interest and encouragement in this work, P. Lonsdale for discussion and for assistance at sea, A. Birket for assistance in the laboratory, and the Ocean Sciences section of the US NSF for financial support.

High explosive analogue of the Tunguska event

THE Tunguska event of 1908, which has been described in detail by Krinov¹, is generally accepted as having been caused by a detonating bolide. Zotkin and Tsikulin² concluded, on the basis of laboratory experimentation, that the event could best be fitted by a travelling wave striking the forest at an angle of 30° to the horizon, culminating in a detonation at a height roughly eight times that of the forest canopy. The pattern of tree blowdown consisted of a radially symmetric zone 35 km in diameter, on which was superimposed a bi-lobed pattern caused by the travelling wave. Stanyukovich and Bronshten³ quote a total energy of 10^{23} erg for the event. In August 1966 an experiment was carried out in a mixed forest of Pine, Spruce and Fir near Hinton, Alberta, Canada, which has some features in common with the Tunguska event. In the experiment a hemispherical stack of TNT, 100,000 lb (50 short tons) in weight, was detonated on the forest floor. The resulting pattern of tree blowdown is shown in Fig. 1.

Fig. 1 Effect of 50-t charge in a mixed forest.

The blowdown zone is 130 m in diameter, and may be compared with the zone of symmetric blowdown at Tunguska. Simple cube root scaling of the dimensions lead to an estimate of 10^3 tons TNT for the Tunguska event. On the basis of a 50% partition of energy, this is equivalent to a 200-kiloton (kt) nuclear event. Taking 1.2 kcal g^{-1} for TNT, the estimated energy for Tunguska is 4×10^{21} erg, two orders of magnitude smaller than the estimate given above. This lower estimate, however, may be a close approximation to the energy of the final detonation, that is to say ignoring the contribution from the travelling wave.

Note, however, that the experiment was a surface explosion, whereas the Tunguska event is believed to be a low 'air burst'. Thus, a refinement of the estimate could be made using the standard height of burst curves. The expected difference in the pattern of blowdown at the full scale—that is, due to a 200-kt detonation at, say, 200 m height—is unlikely, however, to approach an order of magnitude, and will probably be closer to unity. In view of the uncertainties inherent in comparing conventional, nuclear and kinetic energy events in terms of their residual effects, such a refinement of the calculation would be quite unjustified.

Body-centred cubic cylinder packing and the garnet structure

ANALYSIS of the symmetry of periodic packings of identical (circular) cylinders has been found to be useful in analysis of crystal structures. To provide a description of a crystal structure, the cylinders are replaced by rods¹ of atoms or groups of atoms. The densest cubic packing of cylinders is of particular interest: we show how the garnet structure can be described simply in terms of this packing.

Periodic packings of simple geometric objects such as spheres and polyhedra have long had an important role in crystal structure description but little attention has been paid to the problem of cylinder packings in this connection. Periodic packings of cylinders with parallel axes or with axes in parallel planes are fairly easy to visualise, but packings with cubic symmetry are less obvious. One of these, described here, is of special importance to the description of complex cubic structures previously considered enigmatic.

In this packing, cylinders in contact with each other lie with their axes parallel to four cubic $\langle 111 \rangle$ directions. A sketch of a fragment of the packing is shown in the figure. The space symmetry group² of the arrangement is $I4_1/a\bar{3}2/d$ ($Ia3d$) so we propose to call it body-centred cubic cylinder (or rod) packing. The fraction of space filled by cylinders in contact is $\sqrt{3}\pi/8 = 0.680$; this is considerably less than for the densest cylinder packing (which is the familiar honeycomb arrangement with hexagonal symmetry) for which the space-filling fraction is $\pi/\sqrt{12} = 0.907$. Nevertheless it seems to be a safe conjecture that this is the densest cubic packing of identical cylinders.

In applying the cylinder packing to crystal structure description we notice that each cylinder axis lies on a threefold symmetry axis so that a characteristic feature of the symmetry is the presence of four non-intersecting threefold axes. Crystal structures that will lend themselves to description in terms of

Fig. 1 A fragment of body-centred cubic cylinder packing viewed down a trigonal axis.

body-centred cubic rod packing will therefore have this symmetry feature: their space group will be one of the cubic subgroups of $Ia3d$. These are $I43d$, $I4_132$, $Ia3$, $I2_13$, $Pa3$, $P4_132$, $P4_332$, and $P2_13$.

A good example of a crystal structure that can be described as a body-centred cubic rod packing is that of the garnets (symmetry $Ia3d$) typified by grossularite, $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$. The structure³ has been known for fifty years, but has so far resisted a simple description. In this structure the anions are arranged around the threefold axes to form infinite rods of alternating and nearly regular triangular prisms (empty) and octahedra (centred by aluminium ions). Arranging such rods in body-centred cubic rod packing accounts for all the anions in the structure and leaves available sites of eightfold and tetrahedral coordination to accommodate the calcium and silicon ions respectively. The cation positions are fixed by the high symmetry so that an 'ideal' garnet structure can be derived in which the rods consist of alternating regular octahedra and prisms of anions. The coordinates of the 96 anions in the unit cell in the general symmetry-related positions $96h$ are then

$$x = (2\sqrt{3} - 3\sqrt{2} + \sqrt{6} - 2)/8 = -0.0411$$

$$y = (\sqrt{6} - 2)/8 = 0.0562$$

$$z = (3\sqrt{2} - 2\sqrt{3} + \sqrt{6} - 2)/8 = 0.1535$$

very close to those found for real crystals, e.g., for berzeliite⁴ ($x = -0.0391$, $y = 0.0522$, $z = 0.1568$).

Other cubic crystal structures that may be described similarly as a cubic rod packing include those of Th_3P_4 (space group $I43d$), $\beta\text{-Mn}$ ($P4_132$), RbAg_4I_5 ($P4_132$), and bixbyite ($Ia3$). A full description of these and related structures and of rod packing in general is in preparation. It would be of interest also to explore the possibility of cubic rod packings occurring in assemblies of rod-shaped biological molecules or even in the structure of organic matter at a high level such as cellular substructure.

Behaviour of mercury species in isolated estuarine sediment samples—growth and decay of methyl mercury during storage

WE have investigated the levels of methyl mercury found in mercury-containing sediments from the River Mersey Estuary, England, as part of our work on the determination and transport of mercury in the environment¹. We now wish to draw attention to the unexpected behaviour of sediment-bound methyl mercury on storage. In the initial stages of this study we experienced difficulty in obtaining consistent methyl mercury values; supposedly identical samples analysed at intervals of a few days gave markedly different results. We, therefore, followed the levels of methyl mercury in selected sediments over a period, to

determine if any change was occurring on storage. We found that the amounts of methyl mercury observed in the stored sediments did not remain constant; initially there is a rise in the amount of methyl mercury observed, and then, after about ten days, the amount present begins to decline to levels which in general only approximate to those originally present. We have observed this phenomenon in nearly all of the Mersey sediments samples we have examined; in two cases where the total mercury levels were $< 1.5 \mu\text{g g}^{-1}$, a rise in methyl mercury levels was not detected. In general the sediments were in fact found to contain quite high total mercury levels (usually between 5 and $8 \mu\text{g g}^{-1}$) and this feature may be a requirement for the effect to be observed.

For each experiment, a bulk sample of sediment was taken from the intertidal zone of the River Mersey Estuary. This sample (of several kilograms weight) was immediately homogenised (by vigorous hand mixing) on site, and divided into a number of subsamples, each of about 120 g. Two or three of these were immediately frozen with solid carbon dioxide or liquid nitrogen.

On return to the laboratory, the frozen samples were thawed and analysed for methyl mercury. The values obtained were considered to be the ambient levels present in the sediment in estuarine conditions. The other samples were analysed at regular intervals, and the methyl mercury found was plotted against the time elapsed since they were collected. The samples were stored in the laboratory, in darkness, and samples were also analysed for total mercury as previously described¹. The samples were sealed in glass containers in anaerobic conditions at room temperature (18°C). In this, and in nearly all other cases, we observed that on analysis over a period of about ten days, the initially identical samples in fact revealed quite different methyl mercury contents. During storage over this period the level of methyl mercury increased quite significantly until a maximum level was observed after the ten-day period. This maximum is normally about 2–4 times that present initially, although on occasions increases between 10 and 15 times have occurred. After about 10 days the level of methyl mercury declined to an equilibrium level over a period of about 30–40 days. Samples were taken from three different locations in the estuary: Hale Point (Map Ref. SJ 471808), Fiddlers Ferry (SJ 563865) and Stanlow Marshes (SJ 448788), and showed similar results. The total mercury level was usually between 5 and $8 \mu\text{g g}^{-1}$. Samples were obtained on four separate occasions during 1975 and 1976.

The method used for the analysis of methyl mercury was adapted from that of Uthe, Solomon and Grift². Sediment samples of 2–5 g were extracted with toluene after treatment with copper sulphate and an acidic solution of potassium bromide. Methyl mercury was then back extracted into aqueous sodium thiosulphate. This was then treated with acidic potassium bromide and copper sulphate following which the methyl mercury was extracted into pesticide grade benzene containing approximately $100 \mu\text{g dm}^{-3}$ of ethyl mercuric chloride as an internal standard. The extract was analysed by electron capture gas chromatography using a Pye 104 chromatograph equipped with a nickel 65 detector. The glass column ($1\text{ m} \times 0.4\text{ cm}$) was packed with 5% neopentyl glycol adipate on Chromosorb G (AW-DMCS). Methyl mercury was measured by comparing the peak heights with standards of methyl mercuric chloride made up in the ethyl mercury–benzene solution. The results were calculated as nanograms of methyl mercury per gram of dry sediment. The detection limit was $1\text{--}2\text{ ng g}^{-1}$. Six replicate analyses of a sample gave a mean value of 15.78 ng g^{-1} with range limits of $15.39\text{--}16.34\text{ ng g}^{-1}$. Recovery of 20 ng of methyl mercuric chloride added in aqueous solution to the sediment at the start of the procedure was better than 97%.

It should be pointed out that no mercury species has been added to these samples during or after collection. Therefore the observation of a growth and decay curve similar in both magnitude and time scale to those observed by other workers³⁻⁶, who had incubated sediments with separately added inorganic mercury compounds, was unexpected. There has been no previous report of growth of methyl mercury in stored sediments unless inorganic mercury has been added during the experiment, and these observations are therefore of relevance to analytical work on samples containing methyl and inorganic mercury. It has also been noted that sediments sterilised, normally by autoclaving at approximately 120 °C, did not produce methyl mercury on incubation with inorganic mercury³. This suggested a microbiological origin for the methyl mercury produced from the previous samples.

A control experiment was then carried out in which a large number of identical samples were collected and homogenised. Half of the samples were sterilised by treatment with an approximate 4% w/w solution of formaldehyde. We did not wish to carry out the sterilisation by autoclaving as this would have led to loss of the methyl mercury initially present and also to a substantial reduction in the amount of total mercury present. Several samples of both sterilised and unsterilised sediments were analysed each day. (This duplication was to compensate for any variation between individual samples.) All of the samples were stored at ambient room temperature (18 °C) in the laboratory. It can be seen from Fig. 1 that there is a

Fig. 1 Analyses of sterilised and unsterilised sediments from Hale Point, for methyl mercury. Total mercury is $7.24 \mu\text{g g}^{-1}$. Results up to day 25 are the mean of eight determinations; results beyond day 25 are the mean of four determinations. Error bars represent range limits for each analysis series. The samples were stored at room temperature (18 °C). —●—, Untreated; ---○---, sterilised samples.

difference in behaviour between the sterilised and unsterilised samples. In addition some of the samples were separately inoculated into various growth media to test for microbiological activity. With the unsterilised samples prolific growth occurred in both aerobic and anaerobic media, whereas the sterilised sediment samples showed no growth in either type of medium. This confirms that the biological activity in the control samples had been destroyed by the sterilisation process used, and Fig. 1 indicates that the initial levels of methyl mercury were not significantly affected.

The growth and decay curve observed in the Fig. 1 for the unsterilised samples was of the same character as we have observed above. But the sterilised samples behaved in an unexpected way in also showing a growth and decay curve, although the maximum level of methyl mercury achieved was significantly smaller.

These observations may be best understood by a consideration of the process of methyl mercury generation in sediments. An equilibrium probably exists between production of methyl mercury from the large excess of inorganic mercury present in the sediments and loss of methyl mercury by evaporation, solution into sediment pore water or by bacteriological degradation⁴⁻⁷. It has also been stated that tidal or other disturbance of natural sediments increases their methylating rates⁸. Such a disturbance would occur on collection and correlates well with our observed initial increase in methyl mercury. When a certain level is reached, however, the methyl mercury then apparently acts as a poison to the methylating species⁹. The mechanism for loss of methyl mercury, however, would continue to operate, possibly in modified form, causing the level to fall gradually. Finally a new equilibrium seems to be reached, but this new steady-state level does not seem to correspond with that found in the estuary in normal conditions.

To explain the smaller growth of methyl mercury in the sterilised samples we suggest that the methylating species (e.g. methyl corrinoids¹⁰) existing in the sediments persists even after the associated organisms that produce it are destroyed by the sterilisation process. This residue then reacts with the reservoir of inorganic mercury present to produce the initial rise again, until it is exhausted and a loss mechanism for methyl mercury predominates. Whereas for the unsterilised samples the methylating species may be biologically generated to allow methylation to continue, this cannot occur for sterilised samples. This scheme fits well the suggested mechanism of methylation as a chemical process with an enzymatic generation of the methylating species¹¹. It should be noted that the loss mechanism for the sterilised samples cannot involve bacteriological activity and this may account for the slightly slower decay rate of methyl mercury in this case. It should also be pointed out that as sterilisation by autoclaving will also destroy the majority of the enzymes and co-enzymes present, no methylation after this method of sterilisation would be expected.

The appearance of excess methyl mercury on incubation of a natural mercury-containing sediment in the laboratory is significant to the previous work on mercury methylation. It suggests that the application of laboratory-derived results directly to natural conditions could, in these cases, be misleading; our analytical results for day 10 if extrapolated directly might lead to the conclusion that natural methyl mercury levels and rates of methylation are much greater than in fact they really are. Work in this area with model or laboratory systems needs to be interpreted with particular caution. As our observations follow the same pattern for samples of different bulk, stored in different containers and at different temperatures, this also suggests that for properly meaningful survey work for methyl mercury the analytical work must be performed within a short time of collection. In the cases where we have not observed the normal pattern, the total mercury concentrations were relatively low. It is possible therefore that these phenomena may only be observable when high concentrations of mercury and organic material are present, that is, in conditions of severe mercury contamination of an already polluted waterway.

We thank the Science Research Council for support for S.F.M., and for the purchase of GLC equipment, and Leicestershire County Council for a research assistantship for P.D.B. We also thank personnel of Imperial Chemical

Maya Formative phase radiocarbon dates from Belize

THE Formative phase of Maya civilisation in Central America, until recently thought to date back no further than ~900 BC, has been extended to at least 2,500 BC by a series of radiocarbon dates from the site of Cuello, Belize, on samples from the 1975 excavations¹. The series included two dates of 1,020–1,050 b.c. (1,250–1,300 BC) from upper levels at the site and one date of 2,050 b.c. (2,600 BC) from a midden overlying the buried land surface. (The convention b.c. for radiocarbon years and BC for calendar years using the bristlecone pine calibration curve is followed here; for the calibration schemes used, see refs 2 and 3.) We report here a further series of 16 dates on samples from the 1976 excavations at Cuello, which confirm the early date for the Maya Formative and which also suggest occupation of the site at an even earlier date, ~3,200 b.c. (4,000 BC).

The florescence of Classic Maya civilisation in the first millennium AD, in the arid Yucatan Peninsula of Mexico and the tropical rainforest of Guatemala and Belize to the south, was preceded by a Preclassic or Formative period still of unknown persistence, beginning with the initial settlement of the Maya lands by sedentary farmers. The Formative is defined by the presence of an agricultural economy, based in Mesoamerica in general on maize, beans, avocado, peppers, squash and root crops. The history of plant domestication in Mesoamerica has been taken back to the eighth millennium b.c. by work in Oaxaca⁴ although settled village life is not known before the third millennium b.c. The introduction of pottery, which is a good indicator of settled life because of its fragility and relative non-transportability, is dated between 2,500 and 2,000 b.c. (3,250–2,500 BC) in several regions of Mesoamerica. The emergence of the first recognisably complex society, that of the Olmec, marked by monumental sculpture and public architecture, occurred after 1,200 b.c. (1,500 BC)⁵.

The site of Cuello, located in northern Belize (formerly British Honduras) at approximately 18°05'N, 88°35'W, is a small Classic Maya ceremonial precinct and settlement located on the crest of the low limestone ridge between the parallel courses of the Rio Hondo and the Rio Nuevo, which flow east of north into Chetumal Bay on the Caribbean coast of the Yucatan Peninsula. To the south of the Classic site, so far only cursorily investigated, lies a series of large platforms; one of these, designated Platform 34 on the site map made in 1975–76 by M. Walton, B. Ah and F. Johnson (Fig. 2 in ref. 6), was investigated in 1975 under the supervision of D. Pring, and yielded the first stratified Early Formative cultural sequence in the Maya Lowlands. A second season of excavation in 1976, supervised by S.D. with the assistance of N. Fradgley and G. Kelsey, resulted

in the exposure of a sequence of buildings set around open patios which are, on the basis of the radiocarbon chronology reported here, the earliest known in the Maya area and among the earliest in Mesoamerica.

The samples for dating were collected during excavation from structural, building fill and midden contexts. In general the concordance between stratigraphy and chronology indicates that organic material redeposited in fill was so used within a short time of the original deposition, but in the case of the three earliest dates reported here, which are stratigraphically anomalous, redeposition many centuries later is posited.

The dates obtained on the 1976 excavation samples are shown in Table 1 together with an indication of the context, associated ceramics and major cultural period, and calibration of the dates on the schemes of Ralph *et al.*² and Clark³. They are also shown in Fig. 1 with the range of 1 and 2 s.d. indicated, correlated with the phases of building construction I–VIII elucidated in the excavation, which form a stratigraphic control on the radiocarbon chronology.

Radiocarbon determinations were made in Los Angeles by R.B. and S. de A. and in Cambridge by V.R.S. and A.P.W., using gas proportional detectors filled with purified carbon dioxide produced by the oxidation of the specimens of partially burnt wood from the excavations. Traces of structural plaster were eliminated by treatment

Fig. 1 Radiocarbon chronology for the Formative Period sequence at Cuello, Belize, ranged against a calibrated scale in calendar years (at right, after Clark³) and construction phases O–IX elucidated in excavation. O, old land surface; D, destruction level. The period of erection of the first dated Maya monuments AD 260–300 is also indicated. Laboratory references and uncertainties are shown in Table 1.

* Datings considered too early for archaeological context.

† Accidental contamination suspected.

with dilute mineral acid, and any humic acid was removed with dilute alkali. Some samples were rather small, and where they yielded insufficient gas to fill the counters, radioactively inert carbon dioxide was added. Samples were counted to a statistical accuracy of 1 s.d. (1σ). The calculated radiocarbon dates quoted are based on the 'Libby' half life for radiocarbon of 5,568 ± 30 yr. Measurement of the stable isotopes ratio ¹³C/¹²C was made on the gas produced from several of the dated samples. The results were very consistent and indicate that samples were of charcoal from normal wood and were not contaminated by carbon of mineral origin.

Our dates consist of nine from the 1975 excavation¹ and 16 from the 1976 excavation. Of these 25, 18 dates are considered to be archaeologically acceptable in their relationship to the site stratigraphy and to each other. Three dates from the 1975 series (UCLA 1985 bc, d and f) are considered too late by more than a millennium to be acceptable, although no certain cause or source of contamination has been found. One 1976 date (UCLA 2102 e) came from a context later suspected of accidental contamination during excavation, and has been set aside as unreliable. Three other dates from the 1976 series (UCLA 2102 b, c and g) are considered too early for the archaeological contexts from which they were recovered, by more than a millennium; these are tentatively ascribed to redeposition of older material, and are discussed below.

The remaining 18 dates provide an internally and stratigraphically consistent radiocarbon chronology for the Cuello site, and through the associated ceramics for the Formative period in the Maya lowlands. Of the 18 dates, 12 are associated with structures and ceramics of the Early Formative Swasey phase, four with the Middle Formative Lopez Mamom phase and two with the Late Formative Cocos Chicanel phase. On the basis of these dates we can propose chronological limits for the three major divisions of the Maya Formative, and also integrate them into the revised stadial model adopted for the sequence in the Valley of Mexico by some scholars⁷.

The central dates for the 12 determinations attributed to the Early Formative range from 2,050 to 1,050 b.c.; the earliest and latest dates in the series have a 1σ of 155 and 160 yr respectively, and taking 2σ as a reasonable outer limit the Early Formative would fall within the period 2,370-730 b.c. The dates for the Middle Formative suggest that the boundary between the two periods does not fall as late as 730 b.c., and we propose that a boundary close to the latest central date be set, at 1,000 b.c. Similarly, at the lower end of the Early Formative we suggest a consonant boundary of 2,000 b.c., although a lowering of this towards 3,000 b.c. with further investigation would not be unexpected in view of the developed ceramic technology at Cuello by 2,000 b.c. and the possibility of earlier occupation mooted below. In terms of calendar years the Early Formative

would span the period 2,500-1,300 bc, coinciding with the limits proposed for the Initial Ceramic period of Mesoamerica in the Valley of Mexico model.

Two other recent radiocarbon dates from Belize also fall within the Early Formative as defined here: a sample obtained by us from the lowest cultural level of the Barton Ramie site in central Belize, associated with ceramics of the early facet of the Jenney Creek ceramic complex, gave a date 3,200 ± 205 b.p., 1,250 b.c., calibrating on 1σ to 1,790-1,320 bc (Q-1575). Another sample, from a wooden post found in the bank of a canal bordering a man-made raised field complex on the Rio Hondo, a short distance west of the Cuello site, yielded a date of 3,060 ± 230 b.p., 1,110 b.c., calibrating on 1σ to 1,650-1,070 bc (1-7877A) (unpublished results of D. Puleston). The Barton Ramie date indicates that by the end of the Early Formative parts of the eastern Maya lowlands were occupied by people making ceramics in a tradition distinct from that of the Swasey complex, while the date from the Rio Hondo raised field suggests that again by the end of the Early Formative at the latest this intensive and organised method of agriculture was being practised in the lowlands. Mollusc evidence from Cuello indicates that swidden agriculture on the limestone ridge was not practised until the beginning of the Middle Formative (unpublished results of L. H. Feldman) so that intensive cultivation may have preceded extensive methods in this region.

The four dates for the Middle Formative are of 1,020, 730, 520 and 235 b.c., the first of these occurring stratigraphically immediately above the final Early Formative levels at the Cuello site and being associated with a burial accompanied by three pottery vessels of transitional Early-Middle Formative type. The 1σ error of 160 yr on this date matches that on the latest Early Formative determination, and the two dates are statistically inseparable. We feel that the phase boundary of 1,000 b.c. is therefore, within the margin of error, acceptable. The date of 235 b.c. does not necessarily indicate an upper limit for the Middle Formative, since the standard deviation of 195 yr is rather large, but a boundary before this date and the earliest Late Formative date of 330 b.c. may be proposed; we suggest that a limit at 400 b.c. will probably lie within the margin of error of a more accurate boundary, when this is established by further determinations. The Middle Formative would then occupy the period 1,300-450 bc in calendar years.

The two dates associated with Late Formative occupation are of 330 and 175 b.c., the latter again not setting a firm upper limit for the period. This upper limit has conventionally been equated with the first appearance of stone monuments bearing hieroglyphic inscriptions in the Maya script, one of the cultural innovations taken as marking the beginning of the Classic period of Maya civilisation. This boundary is currently set between AD 250 and 300 in

the Maya lowlands, and we therefore suggest that the formal bounds of the Late Formative be set at 400 b.c. (450 bc) to AD 250, the latter limit being calculated only in calendar, and not radiocarbon, years from the basis of the evidence by which it has been set.

Although the Middle-Late Formative boundary and the span of the Late Formative might seem to be based on rather less evidence than for the earliest part of the sequence, the limits which we propose are supported by the radiocarbon chronology for the site of Tikal, Guatemala (19 dates in the Middle and Late Formative) and by smaller numbers of dates from other sites including Dzibilchaltun, Aguacatal, Altar de Sacrificios and San Felipe.

We have therefore suggested that, in comparison with the currently accepted framework for the Formative, the Late Formative should begin some 150 yr earlier, the transition between Middle and Early Formative be placed some 500 yr earlier and the formal beginning of the Early Formative be moved back 1,000 yr, in calendar years.

This latter boundary remains the least certain, however. Three of the radiocarbon dates from the 1976 excavations at Cuello are earlier, at 2,790, 3,190 and 3,190 b.c. (3,575, 3,980 bc). The samples of burnt wood from which the dates were obtained occurred in contexts, in two cases structural and in one building fill, from which both later radiocarbon dates and pottery were obtained that fit well into the proposed Early Formative chronology of the site beginning in 2,000 b.c. (2,500 bc). There is no reason for supposing that the early dates are the result of mineral carbon or laboratory error, and we must thus accept that the burnt wood was indeed of the age indicated by the radiocarbon dates. From this it follows, although there is no external corroborative evidence, that the wood must have been reused or redeposited by the Early Formative inhabitants of the site many centuries after it ceased to grow, and in view of the perishability of uncarbonised wood in a tropical lowland soil, probably many centuries after it was charred. If we accept this, there are two methods by which this charring could have occurred: a natural bush fire, and burning by man, on at least two occasions separated by some four centuries. Although there is no internal evidence to support the anthropogenic origin of the burning rather than the natural, such an explanation would correlate with suggested human interference with the vegetation of Peten, Guatemala, 150 km south-west of the Cuello site (unpublished results of F. Wiseman). In addition, the developed nature of the Swasey ceramic complex at Cuello by 2,000 b.c., and the lack of a credible immediate ancestry elsewhere in the Americas (unpublished results of D. Pring) suggest that earlier occupation of the Maya lowlands, if not the Cuello site itself, remains to be discovered. Although the evidence for human presence in the Maya Lowlands in the fourth millennium bc is still sparse and questionable, it is no more so than the totality of evidence for the Early Formative was only two years ago, and the latter is, we would maintain, now tolerably well established.

Natural selection for energetic efficiency and the relationship between activity level and mortality

A RELATIONSHIP between mortality and metabolic rate may be the basis of a powerful mechanism for the evolution of efficiency in animal locomotion. The ideas presented here were suggested by telemetric observations of brown trout (*Salmo trutta* L.) in their natural environment¹ but may be applicable to a very wide range of animals.

That energetic efficiency is adaptive is an implicit tenet in much recent zoological thought despite the absence of a direct causal link between metabolic efficiency and success in producing offspring. Alexander² describes a simple model for natural selection for efficiency based on the assumption that energy saved in locomotion, for example, is diverted into gonad development so that the efficient genotype produces more offspring. He derives a coefficient of selection of 0.015 for a genotype with non-gonad energy requirements reduced by 1%. This model involves a number of simplifying assumptions and it is clear that increase in gonad products beyond a certain optimum can be disadvantageous³. Selection pressure for efficient energy utilisation may be rather low, any efficiency ratio permitting long term positive energy balance being feasible.

Any animal must function within its 'scope for activity' as defined by Fry⁴. Enforced activity above or below the limits of scope implies certain death. A fish working at moderate power outputs can be assumed to have a small probability of mortality by predation, disease, failure of homeostasis and so on. As the metabolic rate approaches the upper or lower limits of scope so the mortality probability must approach 100%. Metabolic rate (MR) can be normalised to a scale with standard metabolic rate (SMR) as 0 and active metabolic rate (AMR) as 1

$$\frac{MR - SMR}{AMR - SMR} = S$$

Potential mortality per day (M_p) as a function of S probably takes a U-shaped form with M_p equal to 100% at $S < 0$ or $S > 1$ (Fig. 1). Increased time spent at high-activity levels approaching the active metabolic rate may be an important stress and mortality factor in natural populations. Attention has recently been directed to the importance of the cost of reproduction in terms of adult mortality resulting from strenuous activity during the breeding season.⁵

In several marine^{6,7} and freshwater⁸ fish tracking studies it has been shown that high swimming speeds are rare. The total energy requirement for swimming in brown trout has been calculated as 4% of the total ingested energy.^{1,9} This low figure suggests little latitude for fecundity increase by virtue of locomotor energy savings discussed above. Figure 1 shows the typical distribution of metabolic rates of brown trout. Activity in excess of $S = 0.8$ always occupied less than 4% time. The total potential daily mortality (M_{pd}) is equal to the product of potential mortality (M_p) and the time (T_s) at each S level, summed over the whole range of S values:

$$M_{pd} = \sum_{S=0}^{S=1} M_p \times T_s$$

The values of M_p are chosen to give $M_{pd} = 0.1\%$; mortality comparable with that of many natural populations.¹⁰

Fig. 1 Activity and mortality in brown trout. *a*, T_s , The typical distribution of time spent at different metabolic rates relative to scope (S , see text). This is based on heart rate telemetry data¹¹ from brown trout in Airthrey Loch, Stirling, Scotland¹. A log-normal distribution was used to fit the curve. $S = 0$ standard metabolic rate. $S = 1$ active metabolic rate. The absolute power or metabolic rate scale is in arbitrary units. M_{ps} , Potential mortality (or failure rate per day) at different values of S . This is a notional distribution based on arguments in the text; no significance is attached to the particular asymmetry or values shown. All calculations are based on the 50 histogram columns shown, each 0.02 S units wide. *b*, Percentage change in total daily potential mortality (M_{pd}) if the total energy expenditure of the fish is reduced by 0.0043% of the total by energy savings at different values of S .

Natural selection consequences of this can be considered. Assume an adaptation appears which reduces drag at a particular speed so that the power required to propel the fish at its maximum cruising speed is reduced by 1%. The time spent at the highest power category can then be replaced by a similar time at a power output 1% lower. In this example the time at $S = 0.99$ is reduced from 0.2% to 0.181% and the time at $S = 0.97$ increases from 0.22 to 0.239. The new value for M_{pd} is 0.0708%; a 29% drop from 0.1% per day. The actual energy saved is only 0.0043% of the total energy expenditure of the fish. If the fish has one year to live until a single spawning the coefficient of selection in favour of the efficient genotype is 0.17 and if it lives to a second spawning a year later the coefficient is 0.244. Thus selection for efficiency can be much more powerful than previously supposed, particularly in long-lived multiple brood animals.

Figure 1*b* shows the change in M_{pd} if the same amount of energy is saved at different levels of S . Reduction of mortality only occurs where the M_{ps} curve has a positive slope. Selection will therefore produce extreme refinement for efficiency at high power outputs but only a small effect at moderate power outputs.

The model in Fig. 1*b* breaks down at low S values since saving energy apparently increases M_{pd} . Energy savings at these S values must consist largely of reduction in standard metabolic rate; that is the $S = 0$ point is shifted to lower absolute power levels. The scope is therefore increased, the crisis of depressed metabolism averted and M_{pd} would decrease.

The penalty of failure to sustain a given activity level is not necessarily death. In the simple case of fish being chased by a

trawl the only escape may be to swim continuously at high speed. Then

$$\frac{\text{Actual mortality}}{\text{Potential mortality}} = C = 1$$

C approaches 1 if: (1) no alternative strategies can be perceived or implemented, alternative resources of food and refuge being important; (2) anaerobic working capacities to escape crises are absent or exhausted; (3) there are no reserves to sustain the animal if it avoids activity and its hazards altogether. The complexities of C should be noted but the main conclusions are not changed. Since C is generally less than 1 the values of M_{ps} in Fig. 1 should be greater than shown. The theory depends critically on the reality of the relationship between M_p and S . Various different shapes of the curve can be envisaged and analogy with engineering reliability theory may be useful in developing the ideas further. Considerations of power capacities and reliability may be more important than energy balance in functional design of animals.

Chromosomal recombination between *Rhizobium* species

THE basis for the symbiotic specificity whereby legumes are nodulated only by rhizobia of the appropriate cross-inoculation group must reside in genetic determinants in both host and bacterium. To analyse the bacterial determinants, crosses between rhizobia of different cross-inoculation groups are necessary. We show here that the sex-factor R68.45 (ref. 1), which promotes chromosomal recombination in *Rhizobium leguminosarum*² can also mediate gene transfer amongst strains of *R. leguminosarum*, *R. trifolii* and *R. phaseoli*. These species nodulate peas, clover and French beans respectively; thus there is the possibility of identifying bacterial genes involved in host specificity. The only previous report of interspecific conjugation in *Rhizobium* described the transfer of a plasmid that determined host specificity in *R. trifolii* and *R. phaseoli*³. There have also been reports of transformation of genes, including those determining specificity, between *Rhizobium* species^{4,5}.

In *R. leguminosarum* *rif* (rifamycin resistance) and *str* (streptomycin resistance) alleles are cotransferred at high frequencies². We made use of this finding in a series of preliminary crosses with *R. leguminosarum* strain 6591 (*ura-14 met-14 rif str* R68.45) as donor to strains of *R. trifolii* and *R. phaseoli* from the culture collection at Rothamsted Experimental Station, Harpenden, England. Crosses were plated on minimal medium supplemented with streptomycin (200 mg l⁻¹) and rifamycin (25 mg l⁻¹) to select for cotransfer of the *rif* and *str* alleles from *R.*

leguminosarum. One strain each of *R. trifolii* (6601) and *R. phaseoli* (1231) able to receive and express *R. leguminosarum* *rif* and *str* alleles was chosen for further study.

Crosses were made between multiply-marked R^+ *R. leguminosarum* strains as donors and derivatives of 6601 and 1231 as recipients and between *R. trifolii* (R68.45) or *R. phaseoli* (R68.45) with *R. leguminosarum* as recipient. The frequencies of transfer of single alleles and of co-transfer of non-selected alleles in the crosses were measured. Recombinants differing from each parent by two or more alleles could be distinguished from colonies which had arisen by single mutation of either parent to prototrophy or to antibiotic resistance. No unambiguous recombinants (frequency $< 10^{-6}$) were found when R68.45 was absent from both input strains.

The frequencies of transfer of all the selected markers in either direction between *R. phaseoli* and *R. leguminosarum* and for most of the markers in crosses between *R. trifolii* and *R. leguminosarum* were similar to those found in crosses between strains of *R. leguminosarum*² (about 10^{-6} per recipient). As was found in crosses between *R. leguminosarum* strains, more than 80% of recombinants contained the R plasmid, compared with about 1% for non-recombinant recipients.

In Table 1 the frequencies of cotransfer of various pairs of alleles in interspecific crosses are compared with those found in crosses between strains of *R. leguminosarum*. In the interspecific crosses *rif* and *str* were cotransferred at high frequency whether *R. leguminosarum* was donor or recipient. Moreover *rif* and *rif*⁺, *str* and *str*⁺ alleles were transferred to and from *R. leguminosarum* at approximately equal frequencies (results not shown) indicating that donor genes replaced corresponding genes in the recipient rather than that partial diploids were formed.

In many bacterial species *str* and *spc* (spectinomycin resistance) genes are closely linked⁶⁻⁸. This was true for the *spc* allele of *R. phaseoli* (*spc-19*); it cotransferred with *rif* and *str* alleles to *R. leguminosarum* at high frequency. When selection was made for *rif* and *str* transfer from *R. leguminosarum* to *R. phaseoli* carrying *spc-19* about 90% of the recombinants were spectinomycin sensitive (Table 1), indicating the presence of a hitherto undetected *spc*⁺ allele in *R. leguminosarum* closely linked to the *rif/str* region. A *spc* allele of *R. trifolii* was unlinked to *rif/str* (Table 1) but mapped between *phe-1* and *trp-18*, as did the *spc-4* allele of *R. leguminosarum* (unpublished observations).

With the exception of *spc-19* the cotransfer frequencies of pairs of alleles in crosses between *R. phaseoli* and *R. leguminosarum* were similar to those found in crosses between strains of *R. leguminosarum* (Table 1). This was true also for several pairs of alleles in the crosses between *R. trifolii* and *R. leguminosarum*. The frequencies of co-transfer of *ura-14*⁺ and of *met-12*⁺ with *phe-1*⁺ from *R. trifolii* were, however, about tenfold lower than those found in crosses between strains of *R. leguminosarum* which carried these alleles. Also, the absolute frequencies of transfer of *ura-14*⁺ and *met-12*⁺ in the *R. trifolii* × *R. leguminosarum* crosses were about ten times lower than those found for other markers. We do not know whether these alleles are located at another region in *R. trifolii* or whether they do map at the same region as in *R. leguminosarum*, but only that the frequency of recombination in this region is reduced in these interspecific crosses.

If we assume that most of the genes between a pair of alleles were also transferred, integrated into the recipient chromosome and expressed, any essential genes within that region in the recipient must be functionally replaceable by corresponding alleles in the donor. This reinforces the idea that the sequence of genes in the three *Rhizobium* species is very similar. This should greatly facilitate gene mapping in these and perhaps in other species of *Rhizobium*.

To determine whether any of the interspecific recombinants had altered host specificity, individual recombinants inheriting at least two donor alleles were used to inoculate plants; the recombinants between *R. trifolii* and *R. leguminosarum* were tested on peas (*Pisum sativum* cv. Dark Skinned Perfection) and white clover (*Trifolium repens* cv. S100 in the collection at the Welsh Plant Breeding Station, Aberystwyth, Wales) and the recombinants between *R. phaseoli* and *R. leguminosarum* were tested only on peas. Although the frequency of multiple crossover events in recombination is unknown, it is likely that most recombinants received the majority of the genes lying between the two selected alleles. This assumption is supported by the finding that in a cross between *R. trifolii* strain 6647 (*rif spc-20* R68.45) and *R. leguminosarum* strain 1156 (*phe-1 trp-18 str*) all *phe-1*⁺ *trp-18*⁺ recombinants also received the intervening *spc* allele from *R. trifolii*. The recombinants all retained the specificity of the recipient and did not acquire that of the donor (Table 2). Thus it seems that genes determining specificity did not reside in the transferred fragments, or, if they did, that they were not expressed in the heterospecific recipient.

Most studies on interspecific and intergeneric recombination have been done on members of the *Enterobacteriaceae*⁹. The main feature of such crosses is the lowered recombination frequency, although in some cases gene sequences are very similar, as in *Escherichia coli* and *Salmonella typhimurium*. A possible explanation for the general lack of reduction in recombination frequencies in the *Rhizobium* interspecific crosses reported here is that the strains were very closely related and had very similar DNA sequences. Another explanation is that recombination mediated by R68.45 is less dependent on DNA homology than is Hfr-mediated recombination in the *Enterobacteriaceae*. On the basis of numerical taxonomy *R. leguminosarum*, *R. trifolii* and *R. phaseoli* are closely related¹⁰; this was the reason for their choice in this study. Preliminary evidence suggests,

*Donor/recipient refers to those parental strains in the crosses which respectively carried and did not carry the R-plasmid R68.45.

†*R. phaseoli spc-19* was used.

‡*R. trifolii spc-20* was used.

NT, Not tested

The genetically marked strains of *R. leguminosarum* were derived from strain 300 (ref. 12). The *R. trifolii* and *R. phaseoli* strains were derived from strains 12 and 3644 of the Rothamsted culture collection respectively. Methods for mutant isolation, media and culture conditions have been described¹¹, as have the methods for the analysis of linkage in crosses². In this work 150 colonies were picked from each selective medium and analysed for non-selected markers.

Table 2 Nodulating ability of interspecific recombinants

Peas were inoculated with the interspecific recombinants as described¹⁴. Clover seeds were surface sterilised with sodium hypochlorite, transferred to slopes of water agar in test tubes and nitrogen-free medium¹⁵ containing the inoculum was added. The clover was grown at 26 °C under fluorescent lights. Clover plants were scored for nodulation after 2–3 weeks and peas after 3–4 weeks. Two or three plants were used for each recombinant tested.

however, that *rif* and *str* alleles of *R. leguminosarum* may be transferred by R68.45-mediated recombination to a strain of the apparently more distantly related species¹⁰, *R. meliloti* (unpublished observations). It is relevant that in certain conditions different *Rhizobium* species may occupy the same nodule in substantial numbers¹¹. Such a situation might provide an opportunity for gene exchange in the wild if a sex factor were present in one of the strains.

The ability of fairly large regions of the chromosome to be transferred between strains within a *Rhizobium* species^{2,12} allows contemplation of the possibility of a rhizobium breeding programme whereby recombinants containing favourable attributes from different parental strains (for example competitiveness for nodulation, high levels of nitrogen fixation, tolerance to certain environments) could be constructed. Such strains might prove superior to the parentals for use as inocula. The finding of interspecific recombination means that the gene pool for the formation of such recombinants need not be restricted to the variation encountered within a single species.

We thank S. A. Hoggan and S. M. Setchell for technical assistance and we would also like to acknowledge the critical comments made by Professor D. A. Hopwood and Dr N. J. Brewin.

Maturation of prefrontal cortex in the monkey revealed by local reversible cryogenic depression

THE emergence of increasingly complex cognitive functions with age is widely assumed to reflect in part the maturation of connections within the central nervous system, but the neural bases of cognitive development have resisted identification. There is some evidence to indicate that the dorsolateral prefrontal association cortex in monkeys

acquires its adult functional capacities over a protracted span of postnatal development^{1–3}. Most of this evidence, however, has come from studies involving surgical ablation. The study of cerebral development in brain-damaged subjects is complicated by anterograde and retrograde degenerative changes, as well as by the possibility of compensatory neural reorganisation which could occur during the weeks or months between surgical ablation and assessment of behavioural performance⁴. It is now possible to study the functions of specific brain sites without producing permanent brain damage by localised cortical cooling, a method which allows reversible inactivation of restricted regions of cortex in otherwise normal animals. The latter are able to serve as their own controls before and after the episodes of cortical hypothermia^{5–7}. This method has previously been used only in research on mature animals. In this study, local hypothermia was produced for the first time in the dorsolateral prefrontal cortex of young, developing rhesus monkeys during repeated assessment of their performance on a delayed-response task. Such performance in adult monkeys is known to be dependent on the integrity of that region⁸. Our findings provide direct evidence that part of the dorsolateral prefrontal association cortex does not become functionally mature until at least 34–36 month of age, that is, close to sexual maturity in this species.

Seven rhesus monkeys (*Macaca mulatta*) aged 9–36 months were trained to perform a 12-s, two-choice delayed response task. After each monkey reached a criterion performance of 90% correct on four consecutive days, cooling chambers were implanted over a portion of the dorsolateral prefrontal cortex^{9,8} in each hemisphere under pentobarbital anaesthesia. The disk-shaped stainless steel cooling probes (12.5 mm diameter) were implanted epidurally, centered 4 mm above the midpoint of the principal sulcus; the dura remained intact except for two small openings through which insulated bead thermistors were inserted to monitor the subdural temperature. Experimental testing began 1 week after recovery from surgery and consisted of repeated sessions in which the subject's delayed-response performance was assessed before, during and after cooling to 20 °C. Each monkey received 100–200 trials in each of the three conditions (precool, cool, postcool) over the course of 10 sessions.

Intracerebral temperature gradients measured during cooling at terminal stages of the experiment revealed that the areas cooled to 20 °C in all brains was limited to tissue directly beneath the probe and included only the superficial banks of the principal sulcus. The depths of that sulcus remained within 2–3 °C of the normal core temperature. In addition there was no significant hypothermia beyond the boundaries and subjacent white matter of the dorsolateral prefrontal cortex. It should be emphasised that no

significant variation was found in the size or locus of the area cooled in relation to age (Fig. 1). In contrast, the behavioural results were clearly age dependent, as shown in Fig. 2, where the monkeys have been grouped according to age. Dorsolateral prefrontal cooling did not impair delayed-response performance in monkeys 9–16 months of age (Group I). This group made a small number of errors during cooling, but this figure did not differ significantly from the number of errors made during postcool trials. A small but significant increment (7%) in errors due to cooling was first observed in monkeys 19–31 months of age (Group II), but cooling-induced deficits comparable in magnitude (23%) with those seen in adult monkeys^{5,6} did not appear until 34–36 months of age (Group III). The percentage of cooling-induced errors exhibited by Group III monkeys was on the average 2.5-fold higher than that exhibited by the monkeys in Group II.

The pattern of increasing sensitivity to dorsolateral prefrontal cooling, apparent in the comparisons among groups of monkeys at different ages, is also demonstrable in the ontogenetic history of individual monkeys. Thus, one monkey (Fig. 3) manifested a significant but relatively small increase in errors during prefrontal cooling at the age of 31 months, whereas 3 months later this same animal exhibited a 2.5-fold increment in the percentage of errors during cooling, while its control performance during this same interval showed a slight improvement.

Fig. 1 Intracerebral temperature gradients in two planes, determined with cortical surface beneath the cooling chamber maintained at 20 °C. Shown are the data from four animals aged 9 (□), 18 (△), 34 (●) and 36 (○) months, respectively. *a*, Gradient recorded tangential to the cortical surface. Least square line through data has slope of 1.57 °C mm⁻¹ and correlation coefficient of 0.989. *b*, Gradient recorded perpendicular to cortical surface. Least square line has slope of 1.51 °C mm⁻¹ and correlation coefficient of 0.995. Since the brains of the youngest and oldest monkeys differed in size by no more than 5%, and the probe placement was identical in all, there was no significant difference with age in the amount or location of the tissue cooled.

The finding that prefrontal cooling did not induce deficits in the Group I monkeys is in agreement with previous reports that even complete resections of dorsolateral prefrontal cortex in infancy do not produce impairments on delayed response¹⁻³. The 23% performance decrement observed in the oldest (Group III) monkeys during cooling is, however, substantially less than the nearly 50% decrement usually seen in adult monkeys with prefrontal lesions. This discrepancy is most likely due to the fact that the cortex in the depths of the principal sulcus, normally included in dorsolateral surgical ablations, was not subjected to cryogenic depression. But, as the magnitude of the cooling-induced impairment in the Group III monkeys is nearly identical to that reported in independent studies of adult monkeys carried out with comparable methods^{5,6}, it seems that the Group III monkeys represent the age at which the dorsolateral cortex, exclusive of the depth of the principal sulcus, reaches functional maturity.

Fig. 2 Delayed response (DR) performance in relation to cryogenic depression of the dorsolateral prefrontal cortex (DLC). Mean % errors on DR trials presented before, during and after DLC cooling for groups of monkeys in the age spans indicated. % DR errors for each animal and condition were subjected to an arcsin transformation, and the transformed data underwent a 3 (age groups) × 3 (DLC cooling condition) factorial analysis of variance with repeated measures on the last-named variable. The main effect for DLC cooling condition was significant ($F(2,10) = 28.1$, $P < 0.001$), as was the age × DLC cooling condition interaction ($F(4,10) = 8.8$, $P < 0.005$). Comparisons of mean DR errors in the different DLC conditions within groups were made using Tukey's (*a*) test with the critical level of $P < 0.01$. Both Groups II (ages 19–31 months, $n = 3$) and III (ages 34–36 months, $n = 2$) made significantly more errors during cooling than either before or after while their performance under the two latter conditions did not differ significantly. In contrast, for Group I (ages 9–16 months, $n = 3$), there were no significant differences in performance among any of the three conditions.

Thus, the present results indicate that a considerable portion of the dorsolateral prefrontal cortex does not participate significantly in the mediation of delayed-response performance during the first 16 months of postnatal life; subsequently, this region participates only minimally until, by 36 months of age, the process of maturation seems to be essentially complete. Previous evidence from ablation studies for the protracted maturation of the dorsolateral prefrontal cortex was open to the alternative explanation that early lesions of this area had failed to result

Fig. 3 % Errors on DR trials presented before, during and after DLC cooling in a single monkey tested at two different stages of development.

in deficits months after surgery because there had been time for recovery of function through compensatory neural reorganisation⁴. This explanation now seems improbable because prefrontal cooling did not produce delayed-response deficits in young, non-lesioned monkeys. In these animals neural reorganisation should not be a factor unless it were assumed that such a process could be stimulated by cortical hypothermia within the course of a testing session.

The lack of dependence on the dorsolateral prefrontal cortex for delayed response behaviour in young monkeys, shown now both in studies of surgical and functional ablation, contrasts with the dependence for such behaviour, from infancy through sexual maturity, on certain brain regions other than the dorsolateral prefrontal cortex, such as the orbital prefrontal cortex^{1,9}, the anterodorsal caudate nucleus¹⁰ and the mediodorsal nucleus^{4,11}. Our results suggest that the dorsolateral prefrontal cortex assumes its mature functions by augmenting rather than replacing these other antecedent neural mechanisms, since there is no evidence of disturbance in the basic ability to perform delayed response during the transition from minimal to maximal dependence upon the dorsolateral prefrontal cortex.

Gene dosage for isocitrate dehydrogenase in mouse embryos trisomic for chromosome 1

It is generally assumed that changes in chromosome number are reflected in gene dosage effects for loci located in the extra or missing chromosomes. Although such effects have been well substantiated in *Drosophila*¹, data for mammalian aneuploidy are scarce. Quantitative gene dosage effects have been demonstrated for several X-linked enzymes in oocytes of mice with X-chromosome aneuploidy^{2,3} and for malic enzyme in mice with partial trisomy of chromosome 7 (ref. 4). In man, similar effects for superoxide dismutase-1 (W. W. Feaster, L. W. Kwok and C.J.E., unpublished and ref. 5), adenine phosphoribosyltransferase⁶, purine nucleoside phosphorylase⁷ and erythrocyte acid phosphatase⁸ have been observed in cells aneuploid for chromosomes 21, 16, 14 and 2, respectively. Aneuploidy for chromosome 21 also affects responsiveness to interferon⁹, and XYY cells have been claimed to have increased amounts of H-Y surface antigen¹⁰. Since the detection of more than 30 metacentric (Robertsonian translocation) chromosomes in wild and laboratory strains^{11,12} and the development of a mating scheme which utilises such translocations for the production of aneuploid embryos in relatively high frequencies^{13,14}, the mouse has become particularly useful for gene dosage studies. We have used

Fig. 1 Metaphase spreads from membranes of trisomic mouse embryos prepared as described by Evans *et al.*¹⁵. a, Trisomy 1; b, trisomy 12. The two metacentric chromosomes indicative of the trisomic state are indicated by arrows in each spread.

this system to demonstrate the dosage effect for supernatant isocitrate dehydrogenase (Id-1) which results from trisomy for chromosome 1.

Males doubly heterozygous for two different metacentric chromosomes which contain chromosome 1, Rb1(1.3)Bnr and Rb10(1.10)Bnr, were obtained by mating animals homozygous for Rb1 with Rb10 homozygotes. To produce embryos trisomic for chromosome 1, heterozygous males were mated with mature white Swiss (WS) females (Simonsen Laboratories), and the time of mating was confirmed by observation of vaginal plugs. For control experiments, embryos trisomic for chromosome 12 or chromosome 19 were generated by using Rb5(8.12)Bnr/Rb9(4.12)Bnr and Rb1(5.19)Wh/Rb163(9.19)H heterozygotes, respectively. These aneuploid embryos are known to be viable until day 14 or 15 of gestation¹⁵. The pregnant females were killed on day 12 or 13, and the embryos (with membranes) were removed. The chromosome constitution of each embryo was determined by examination of metaphase spreads made after short term incubation of the membranes in colcemid as described before¹⁵. Trisomic embryos were identified by their two metacentric chromosomes and total of 41 chromosome arms. Because monosomic embryos die at or shortly after implantation¹⁶, all other karyotypes with only one metacentric chromosome are euploid. As Table 1 shows, between 15 and 42% of the embryos were trisomic. Representative metaphases from trisomic embryos are shown in Fig. 1.

While the membranes were being prepared for chromosome analysis, the individual whole embryos were homogenised and analysed for enzyme activity spectrophotometrically and, when appropriate, by starch gel electrophoresis. The results of assays for Id-1 activity in embryos trisomic for chromosome 1, 12 or 19, and for glucose-6-phosphate dehydrogenase (G6PD, X-linked) and 6-phosphogluconate dehydrogenase (*Pgd*, chromosome 4) in trisomy 1 embryos are summarised in Table 1. Control embryos were the karyotypically normal embryos from the same litters as the trisomics. Trisomy 1 was associated with 1.53 ± 0.04 (s.d.) times the control activity of Id-1, but neither G6PD or *Pgd* activity was significantly different from the control. Thus trisomy 1, with three chromosome 1 instead of two, results in the expected 3:2 increase in activity of chromosome 1-determined Id-1, but not of enzymes coded by other chromosomes; trisomy for either of two other chromosomes does not affect the activity of Id-1.

Given the observed Id-1 activity in trisomy 1, it would

Table 1 Enzyme activities in trisomic embryos

Mating	Chromosome	Trisomy Frequency	Enzyme activity in trisomic embryos (ratio to normal)		
			Id-1	G6PD	PGD
WS × Rb1Bnr/Rb10Bnr	1	14/91 (15%)	1.53 ± 0.04 (6)	0.96 ± 0.05 (5)	0.94 ± 0.26 (5)
WS × Rb5Bnr/Rb9Bnr	12	7/23 (30%)	1.06 ± 0.05 (4)		
WS × Rb1Wh/Rb163H	19	11/26 (42%)	0.98 ± 0.06 (7)		

Results are expressed as mean $\pm$ s.d. of the ratios of specific activities based on soluble protein. The number of determinations is shown in parentheses. Each embryo was individually homogenised in a plastic tube (6 × 50 mm) with a glass homogeniser in 0.05 ml 0.25 M sucrose in 0.01 M phosphate buffer, pH 7.0. Another 0.05 ml sucrose-phosphate was added, and the homogenate was then centrifuged at 27,000g for 20 min at 4 °C. The supernatant fluids were used for enzyme assay and protein determinations. Id-1 was assayed as described by Lowry and Passonneau¹⁸, and G6PD and PGD as described by Glock and McLean¹⁹.

be expected that each of the three genes for Id-1 contributes equally to the total product. To test this directly, the enzyme produced by trisomic and normal embryos was subjected to starch gel electrophoresis. Since Rb1Bnr carries the *b* (fast) allele at *Id-1* and Rb10 the *a* (slow) allele, the Rb1/Rb10 heterozygote is electrophoretically *ab*. Depending on the allele contributed by the Swiss female, which can be either *a* or *b*, the genotype for the Id-1 of the trisomic embryos will be either *aab* or *abb*. Because Id-1 is a dimer, the possible enzyme products are *aa*, *ab* and *bb*. If each gene is functionally equal, the expected ratios of the three are 4:4:1 (if the embryo is *aab*) or 1:4:4 (if *abb*). Normal embryos will be *aa*, *bb* or *ab*, and the electrophoretic patterns will show either pure *aa*, pure *bb*, or *aa*, *ab* and *bb* in a 1:2:1 ratio. As Fig. 2 shows, patterns compatible with the expected trisomic and normal patterns were observed. Furthermore, no patterns suggestive of the presence of three operative *Id-1* genes were observed with embryos trisomic for chromosome 12. Thus the biochemical data are consistent with an exact and specific dosage effect for Id-1 in trisomy 1.

With the large number of mouse translocations which have been identified and which are being placed on inbred backgrounds^{13,17}, it will soon be possible to produce and investigate embryos and cell lines derived from them which are trisomic for most of the mouse autosomes. This approach, of which this report is an example, should permit a systematic and refined examination of the molecular and developmental consequences of chromosome imbalance.

Fig. 2 Electrophoretic patterns of Id-1 from normal (N) embryos and embryos trisomic (T) for chromosome 1. Electrophoresis was carried out in an 11% vertical starch gel for 20 h at 4 °C at a constant voltage of 120 V using the citrate-phosphate buffer system (No. 3) of Ruddle and Nichols²⁰. The gels were stained as described by Henderson²¹. The origin (O) is at the top and the samples were run to the anode (+). The two trisomic embryos show patterns compatible with the expected 1:4:4 and 4:4:1 ratios for the *abb* and *aab* genotypes, respectively. The five normal embryos display the pure *a*, pure *b*, or 1:2:1 patterns compatible with *aa*, *bb* or *ab* genotypes, respectively. The standard (S) for the *a* (slow) allele was obtained from a liver homogenate from a BALB/c mouse.

Heparin-like inhibitor of blood coagulation in normal newborn

THE level of the blood coagulation factors in the newborn is known to be markedly lower than that in the adult. Generally this is attributed to a lack of synthetic capacity of the liver and a deficiency in vitamin K. We describe here a re-investigation of this problem making use of recently developed methods that determine both the coagulation factors and the abnormal proteins induced by vitamin K absence (PIVKAs). We found low coagulation factor activity in the newborn but no evidence for vitamin K deficiency. In more than half the samples a hitherto unrecognised inhibitor of blood coagulation could be demonstrated. At 3 d of age this inhibitor was found in all babies investigated. On the basis of its properties in blood coagulation tests the inhibitor could not be distinguished from heparin.

In 43 healthy newborns a 20-cm piece of umbilical cord was clamped directly after birth and 9 ml of blood was withdrawn by puncture from the vena umbilicalis into a polypropylene syringe containing 1 ml of a solution containing HEPES 0.3 M, trisodium citrate 0.1 M, sodium azide 15 mM, Trasylol (Bayer) 50 U, pH 7.3. This mixture effec-

tively prevents fibrinolysis. Plasma was obtained by centrifugation and spun platelet poor by a second centrifugation (30 min 4 °C, 20,000g). It was frozen in 1-ml aliquots and stored at -20 °C until further use. In these plasmas we determined clotting factors V, VII, and X and prothrombin by a one-stage procedure and prothrombin also by a two-stage procedure (Table 1). Experimental methods were as described in ref. 1.

In 27 of the 43 plasmas the disappearance rate of thrombin in the two-stage prothrombin assay was significantly (>5 times) greater than in normal human adult plasma. In the 16 others it was no more than 1.8 times greater than normal. On the basis of this observation we divided the plasma in an inactivated and a non-inactivated group. We found no significant differences in antithrombin III, α_1 -antitrypsin, α_2 -macroglobulin, antiplasmin, C₁-esterase inhibitor and inter- α -trypsin inhibitor activities between inactivated and non-inactivated plasma samples: we therefore conclude that none of these proteins are responsible for the inactivation. No fibrinogen degradation products could be detected in either of the plasmas. Pooled inactivated and pooled non-inactivated plasma was diluted 20-fold with distilled water; isoelectric precipitation at pH 5.2 yielded a fraction containing prothrombin but no thrombin inhibitors. In such fractions made from both plasma types, thrombin generated normally and was not inactivated. In the presence of normal plasma the thrombin thus generated inactivated normally. This excluded the possibility that the rapid inactivation was due to an abnormality of the (pro)thrombin molecule in the inactivated plasma.

Both procoagulants and thrombin inactivating proteins in inactivated plasma were precipitated by phosphotungstic acid (1/3 volume of 10% phosphotungstic acid in 0.67 N H₂SO₄). After neutralisation and removal of the phosphotungstic acid, the resulting fraction accelerated thrombin inactivation in normal plasma by a factor five to seven, and lost its inactivation enhancing properties on addition of 12 μ g ml⁻¹ protamine sulphate. No such fraction could be obtained from the non-inactivated plasma. Inactivation of thrombin in inactivated plasma could be prevented by addition of 14 μ g ml⁻¹ of protamine sulphate whereas such addition had little or no effect on non-inactivated plasma.

Heparin is known to potentiate thrombin inactivation by antithrombin III, to be neutralised by protamine sulphate and not to be precipitated by phosphotungstic acid².

We conclude that the inactivated plasma contains heparin or a substance with heparin-like properties. The source of this substance is presumably in the newborn. It could not be demonstrated in maternal blood or in the perfused placenta. Five children who did not show enhanced inactivation in

Fig. 1 Thrombin generation and breakdown in pooled newborn plasmas with (○) and without (●) inactivating substance. Reaction mixture: 0.2 ml plasma, 0.1 ml human brain thromboplastin, 1.7 ml Michaelis buffer pH 7.2, 1 ml CaCl₂ 33 mM. At the times indicated 0.1 ml of the reaction mixture was subsampled into 0.1 ml of BaSO₄ adsorbed plasma diluted 1:5 with Michaelis buffer (pH 7.2). From the clotting time obtained the thrombin content was calculated¹.

the cord blood did show this activity in blood taken from the vena cubiti on day 3 of life. The 11 others from the non-inactivated group were not tested.

Presumably this heparin-like substance is produced in organs that are hardly perfused before birth, but will have an active circulation afterwards (that is, the lungs). It may serve to prevent thrombosis in these organs. In this context it is interesting to note that complete deficiency of antithrombin has never been observed although several series of (possibly heterozygous) patients with about a half normal amount of antithrombin III have been reported³. Complete absence of antithrombin III which would prevent the action of the heparin-like substance might be a lethal condition.

We found no differences between the inactivated and non-inactivated groups in any of the coagulation factors tested. More interesting, there was no discrepancy between the prothrombin contents found with the one-stage and the two-stage assay (Table 1). This indicates that no proteins induced by vitamin K absence (PIVKAs) are present in the plasma of the newborn⁴. This is corroborated by the fact that neither in the staphylocoagulase test nor in the Echis Carinatus test nor in a one-dimensional immuno electrophoresis an excess of prothrombin activity was observed whereas the PIVKA when present would co-estimate in these tests (Table 1, ref. 1).

We concluded that, contrary to current beliefs, the newborn has no vitamin K deficiency but is 'anticoagulated' by heparin or a heparin-like substance.

Abrogation of reaginic antibodies with modified allergens

ALLERGIC diseases such as hay fever, extrinsic asthma, drug hypersensitivities and some forms of urticaria are mediated by allergen-specific antibodies of the IgE class, known also as reagins. Specific suppression of the IgE antibodies to haptens and protein antigens has been achieved recently by injection of conjugates of haptens with non-immunogenic carriers¹⁻⁵ or by appropriately modified allergens⁶⁻⁸. Here we describe a new method for converting a well defined protein antigen, such as ovalbumin (OA), or the mixture of the non-dialysable allergenic constituents of the aqueous extract of ragweed pollen (RAG), to tolerogenic and non-allergenic products which are capable of abrogating the primary as well as ongoing IgE responses to the corresponding native allergens in B₆D₂F₁ mice and rats. Our method involves the covalent coupling of the allergens to the non-immunogenic, hydrophilic polymer, polyethylene glycol (PEG); this approach was inspired by the report that coupling of PEG to catalase and bovine serum albumin resulted in loss of the immunogenicity of these proteins⁹.

In the present study two batches of PEG (Fisher Scientific Company, New Jersey, USA) with average molecular weights of 6,000 and 20,000, referred to as PEG₆ and PEG₂₀, were coupled to OA and RAG using cyanuric chloride as the coupling reagent¹⁰. After a number of trials, it was shown that PEG-antigen conjugates, possessing the required tolerogenic capacity, were prepared by adding cyanuric chloride (0.2 g in 3 ml of *N,N'*-dimethylformamide) to a mixture of 0.4 g of PEG dissolved in 6 ml of 0.5 N NaOH and 0.1 g of OA or RAG in 5 ml of phosphate-buffered saline, pH 7.2. These conjugates were separated from the original reactants by filtration through Sepharose 4B. The chemical characteristics of these conjugates were not studied in detail in these exploratory investigations and chemically well defined PEG-antigen conjugates, differing in the number and molecular weight of PEG molecules grafted on to each antigen molecule, are currently being synthesised.

Optimal anti-DNP and anti-OA IgE responses were induced in B₆D₂F₁ mice and in Chester Beatty rats and IgE responses specific for RAG, antigen E of RAG and the antigens of the extract of *Ascaris suum* (Asc) were induced in B₆D₂F₁ mice by procedures similar to those described previously^{4,11}. Serum IgE levels were determined by passive

Fig. 1 Suppression of the reaginic antibody response with OA-PEG₆. Test mice were injected i.v. with 1 mg of OA-PEG₆ 4 h before receiving the first sensitising dose of DNP-OA on day 0. The mice received i.p. a second sensitising dose of antigen on day 28 without further administration of the conjugate. Δ — Δ , Anti-OA, IgE response; $\circ$ — $\circ$, Anti-DNP IgE response.

cutaneous anaphylaxis (PCA) assays in random-bred hooded rats⁴.

Intravenous (i.v.) administration of 1 mg of OA-PEG₆ into mice 4 h before immunisation with 1 μ g of DNP₃-OA in Al(OH)₃, referred to as the sensitising dose of DNP-OA, suppressed completely the primary anti-DNP and anti-OA IgE responses and these mice responded very poorly to a further sensitising dose of DNP-OA (Fig. 1). By contrast, injection of 1 mg of free PEG₆ or PEG₂₀, or of OA which had been treated with cyanuric chloride in absence of PEG, had no effect on the ability of the animals to mount IgE responses to DNP-OA. The specificity of the immunosuppression was demonstrated by the results listed in Table 1. Thus, whereas treatment of mice with OA-PEG₆ suppressed profoundly their ability to produce IgE antibodies to both DNP and OA on sensitisation with DNP-OA, it did not affect their capacity to produce IgE antibodies to both DNP and Asc on immunisation with DNP-Asc. Hence, the mechanism of immunological suppression induced by OA-PEG seems to operate at the level of cells interfering with the normal cooperation between helper T cells and B₆ cells¹².

In relation to the potential use of PEG-allergen conjugates for the immunotherapy of allergic individuals, it is to be noted that i.v. injection of OA-PEG conjugates into mice presensitised with DNP-OA led to the suppression of their ongoing anti-DNP and anti-OA reaginic responses.

Table 1 Specificity of immunosuppression with OA-PEG

Group	Treatment		Day	Primary immunisation			Day	Secondary immunisation		
	Day 0	Day 28		Anti-DNP	Anti-OA	Anti-Asc		Anti-DNP	Anti-OA	Anti-Asc
Control A*	DNP-OA	DNP-OA	14	1,000	1,000	NT	35 42	3,310 1,280	3,500 3,020	NT NT
Test A†	OA-PEG ₆ plus DNP-OA	DNP-OA	14	< 10	< 10	NT	35 42	80 480	480 860	NT NT
Control B*	DNP-Asc	DNP-Asc	14	890	NT	200	35 42	1,000 640	NT NT	1,500 840
Test B‡	OA-PEG ₆ plus DNP-Asc	DNP-Asc	14	600	NT	180	35 42	1,650 780	NT NT	1,700 640

*Mice in control groups A and B received on each of days 0 and 28 a sensitising dose of DNP-OA or 10 μ g of DNP-Asc in Al(OH)₃, respectively.

†Mice in test group A received an i.v. injection of 800 μ g OA-PEG₆ 4 h before administration of the sensitising dose of DNP-OA on day 0 and were challenged with the same dose of DNP-OA on day 28.

‡Mice in test group B received an i.v. injection of 800 μ g OA-PEG₆ 4 h before sensitisation with 10 μ g DNP-Asc in Al(OH)₃ on day 0 and were challenged with the same dose of DNP-Asc on day 28.

§Groups of four to five mice were bled on day 14 for the determination of the primary IgE response and on days 35 and 42 for assessing the level of IgE antibodies in the secondary response; the sera of each group were pooled prior to PCA testing (NT, not tested).

Table 2 Induction of tolerance in rats with OA-PEG₂₀

Group	Treatment*	Rat no.	PCA Titres†		Systemic Reaction‡
			Anti-DNP	Anti-OA	
Control	DNP-OA + Al(OH) ₃ + 10 ¹⁰ <i>B. pertussis</i>	1	90	80	Death in 24 min
		2	260	100	Death in 33 min
		3	260	100	Death in 36 min
		4	270	80	Death in 28 min
Test	OA-PEG ₂₀ and DNP-OA + Al(OH) ₃ + 10 ¹⁰ <i>B. pertussis</i>	5	<10	<10	No symptoms
		6	20	20	No symptoms
		7	<10	<10	No symptoms
		8	<10	<10	No symptoms

*All rats were sensitised i.p. with 1 µg DNP₃-OA in presence of 1 mg Al(OH)₃ and 10¹⁰ *Bordetella pertussis*; the rats in the test group received an additional i.v. injection of 2.5 mg of OA-PEG₂₀ 4 h before sensitisation.

†The PCA titres refer to the reaginic antibodies in sera of rats 14 d after sensitisation.

‡Rats were challenged i.v. with 2 mg of OA in 1 ml PBS 14 d after sensitisation.

Similarly, the administration of either RAG-PEG₆ or RAG-PEG₂₀ into mice, which had been sensitised with RAG, abrogated their ongoing anti-RAG IgE response and further sensitisation with RAG did not restore their anti-RAG IgE antibody levels (Fig. 2). The results given in Table 2 indicate that tolerance was also induced in rats by i.v. injection of OA-PEG₂₀ 4 h before sensitisation with DNP-OA and, most significantly, whereas rats made tolerant by this treatment did not show any discomfort on i.v. challenge with OA, the control-sensitised rats died of anaphylaxis after receiving OA.

In addition to being tolerogenic, PEG-allergen conjugates were shown to be devoid of the ability to react with antibodies to the unmodified allergens. Thus, these conjugates failed to combine with antibodies to the native allergens, as proven by their inability (1) to neutralise *in vitro* IgE antibodies to the unmodified allergens (demonstrated by PCA as described in ref. 13), (2) to give precipitin bands with rabbit antisera specific for the native allergens, (3) to induce anaphylaxis in sensitised rats and (4) to trigger PCA reactions in skin sites sensitised with IgE antibodies to the native allergens. Moreover, it is noted that the lack of allergenicity of RAG-PEG₂₀, was also confirmed with respect to human reagins to RAG. Thus, in experiments involving the direct skin testing of a RAG-sensitive individual and PCA testing of a rhesus monkey sensitised with a reaginic serum of a patient allergic to RAG, RAG-PEG₂₀ was shown to be essentially devoid of the allergenicity of native RAG. Hence, PEG conjugates of common allergens may prove to be useful therapeutic agents for the abrogation of IgE-mediated allergies without unleashing anaphylactic reactions. The lack of allergenicity and antigenicity of these tolerogenic PEG conjugates was also paralleled by their non-immunogenicity, that is, their

inability to induce an antibody response in normal mice in absence of adjuvants.

After induction of tolerance with PEG-antigen conjugates in mice, the state of unresponsiveness could be maintained even after transfer of tolerised spleen cells into X-irradiated recipients, that is, challenge of the recipients with a sensitising dose of the antigen failed to elicit a secondary response. Furthermore, the results of more recent experiments indicate that the suppressive effects due to PEG-modified antigens were caused by suppressor cells specific for the determinants of the carrier portion of the native antigens. This observation is in agreement with the recent demonstration⁷ that urea-denatured antigen E of RAG also generated suppressor T cells and one may, therefore, suggest that an antigen in a non-immunogenic form favours the proliferation of T suppressor cells. The cellular mechanism underlying the observed suppression of the IgE response by PEG-antigen conjugates remains to be elucidated with chemically better defined PEG-antigen conjugates. We expect that the number and molecular weight of PEG molecules grafted on to each antigen molecule would affect the structure of the determinants of the antigen as well as their accessibility to the free and cell membrane-bound immunoglobulins and to receptors on helper, suppressor and accessory cells involved in the overall immune response.

These studies were supported by the Medical Research Council of Canada.

Note added in proof: It has been recently reported¹⁴ that coupling of antigen E of RAG to PEG of molecular weight 2,100 resulted in pronounced reduction of the allergenicity and immunogenicity of this antigen. No indication was given if this conjugate was immunosuppressive, which is the most prominent feature of the conjugates prepared by us.

Retinyl acetate inhibits mammary carcinogenesis induced by *N*-methyl-*N*-nitrosourea

THE use of pharmacological agents to prevent development of epithelial cancer is attracting increasing attention. Recent studies have shown the successful use of vitamin A and its synthetic analogues (together known as retinoids) for this purpose^{1,2}. We have shown that both natural and synthetic retinoids (retinyl acetate and retinyl methyl ether, respectively) markedly inhibit mammary carcinogenesis induced in the Sprague-Dawley rat by 7,12-dimethylbenz[*a*]anthracene (DMBA) (refs 3, 4). Although the DMBA model has contributed significantly to the understanding of mammary carcinogenesis, particularly hormone responsiveness, the model is less than ideal in that the tumours only rarely invade surrounding tissues and do not metastasise. A new mammary carcinogenesis model, first described by Gullino *et al.*⁵, using intravenous injection of *N*-methyl-*N*-nitrosourea (NMU) in the Buffalo rat, satisfies the deficiencies of the DMBA model in that cancers are exclusively localised in the mammary gland, are hormone dependent, show metastasis to other organs, are transplantable, and result in hypercalcaemia. NMU also causes a high incidence of mammary cancers in female Sprague-Dawley and Fischer-344 rats⁶, but the biological characteristics of the cancers in these strains have not been described in detail. But, our preliminary studies using Sprague-Dawley rats indicated that NMU-induced mammary cancers are highly aggressive and similar histologically to those induced in the Buffalo rat. The NMU model of mammary cancer thus resembles the human disease more closely than the DMBA model. We describe here a study of the effect of a retinyl acetate on mammary carcinogenesis induced by NMU, using a modification of the procedure reported by Gullino *et al.*⁵. We show that retinyl acetate inhibits carcinogenesis in this system.

Female rats of the Sprague-Dawley strain were obtained when 42 days of age. All the animals initially received stock diet (Wayne Lab Meal) and tap water *ad libitum*. NMU was dissolved in physiological saline (20 mg ml⁻¹) which had been adjusted to pH 5.0 with a few drops of 3% acetic acid. Rats (50-d-old; average weight 150 g) were injected intravenously with NMU at 5.0, 2.5, or 1.25 mg per 100 g of body weight (Table 1). Control animals received saline alone. Each NMU-treated and control rat received a second injection 7 days later. Three days after the second injection, all rats were placed on the diets indicated in Table 1 for the remainder of the experiment. Retinyl acetate was blended into the stock diet in the form of stable gelatinised beadlets at a concentration of 250 mg

retinyl acetate per kg diet; rats in groups 1, 3, 5, and 7 received the control gelatinised beadlet material without retinoid (placebo beadlets). All rats were palpated twice each week for detection of mammary tumours, and were also weighed twice each week and observed daily for evidence of retinoid toxicity. At 175 days all animals were sacrificed and the mammary tumours removed and processed for histological classification. More than 75% of the tumours (Table 1) were adenocarcinomas, which were highly aggressive, contained many mitotic figures, and were invasive to the pectoral muscle. Metastasis to the kidney was found in one rat in group 5. A few benign tumours were also seen, and these were either adenomas or fibroadenomas.

No mammary tumours developed in animals which received no carcinogen. Animals receiving the high dose of NMU and fed placebo diet (group 3) had a mammary cancer incidence of 83% (Table 1), while animals treated with this dose of carcinogen and fed retinyl acetate had a mammary cancer incidence of only 50% (group 4). A similar reduction in the incidence of mammary cancer was found in rats receiving retinyl acetate and the intermediate dose of NMU (group 6 compared with group 5). No mammary cancer developed in those rats receiving the low dose of NMU and retinyl acetate (group 8), while the animals treated with this dose of NMU and placebo diet (group 7), had a 20% incidence of cancer. Although this incidence of mammary cancer in group 7 might be considered relatively low, it is more than twice that found in the total population of women at risk in England or the United States⁸.

In addition to reducing the incidence of mammary cancer, retinyl acetate also caused a marked reduction in the total number of cancers, as well as benign tumours (Table 1). Furthermore, the administration of retinyl acetate greatly prolonged the latency period of mammary cancer at all three doses of NMU. As shown in Fig. 1, the time of appearance of the first palpable cancer in rats treated with the high dose of NMU was doubled by the administration of retinyl acetate. With the low dose of carcinogen, the first palpable cancer appeared at 107 days, whereas animals fed retinyl acetate after the low dose of NMU were free of mammary cancer on termination of the experiment at 175 days.

The mechanism by which retinoids, both natural and synthetic, protect against mammary carcinogenesis is unknown. Here, cancer prevention was not due to an inhibition of initiation of cancer, since feeding of retinyl acetate was not begun until after all free carcinogen had disappeared. The half life of NMU at body pH is only a few hours⁷. Moreover, inhibition of carcinogenesis did not result from some general toxic effect of retinyl acetate, as 'hypervitaminosis A' (ref. 8) was not observed. At necropsy,

Table 1 Effect of retinyl acetate on mammary carcinogenesis

Female Sprague-Dawley rats received either saline or NMU in saline (5.0, 2.5, or 1.25 mg per 100 g body weight) by i.v. injection at 50 d of age. A second injection was administered one week later. The animals were placed on either retinyl acetate (250 mg per kg of diet) or placebo beadlets 3 d after the second injection and sacrificed 175 d after the initial NMU injection.

*Significantly different from respective placebo control group, $P < 0.05$ or better.

Fig. 1 Effect of retinyl acetate on the time of appearance of palpable mammary cancers which were confirmed histologically at necropsy. Rats were placed on retinyl acetate or placebo diet 3 d after the second i.v. injection of either 5.0 mg or 1.25 mg NMU per 100 g body weight. The rats were palpated for mammary tumours twice weekly for the duration of the experiment. Treatments were: ○, high dose NMU, placebo diet; ●, high dose NMU, retinyl acetate diet; △, low dose NMU, placebo diet; ▲, low dose NMU, retinyl acetate diet.

body weight and liver histology of rats fed retinyl acetate were essentially identical to those fed placebo diet. Vaginal smears from rats fed retinyl acetate revealed normal oestrous cycles, suggesting that metabolism of ovarian steroids was not significantly altered. Although the fundamental effects of retinoids in maintenance of normal epithelial cell differentiation (even in tissues exposed to carcinogens *in vitro*^{9,10}) suggest that this process may be the mechanism of inhibition of carcinogenesis^{1,2}, other effects on the endocrine or immune system cannot be ruled out at the present time.

The present data demonstrate the efficacy of retinyl acetate in prevention of experimental mammary cancer. Although retinoid toxicity was not seen in these studies, the potential toxicity of retinyl esters, such as retinyl acetate or retinyl palmitate^{8,11}, makes the development of new synthetic retinoids, with greater activity and lesser toxicity, of significant importance.

We thank Hoffmann-La Roche for supplying retinyl acetate in beadlet form; Dr Henry Thompson, Mr Lawrence Dooley, and our staff for expert assistance; and Dr Pietro Gullino for criticisms. This work was supported in part by contract NO CP 23293 from the Division of Cancer Cause and Prevention, NCI.

Synthetic polyamines added to cultures containing bovine sera reversibly inhibit *in vitro* parameters of immunity

POLYAMINES are present in high concentration in foetal¹ and neoplastic tissue² and seminal fluid³—all representing antigenic challenges which usually fail to elicit the appropriate immune response. This has prompted us to investigate the influence of polyamines on *in vitro* parameters of immunity. We report here that micromolar quantities of spermine and spermidine reversibly inhibit three responses of primary cultures of murine spleen cells. These are (1) DNA synthetic response stimulated by phytohaemagglutinin (PHA), pokeweed mitogen (PWM), concanavalin A (con A) or bacterial lipopolysaccharide (LPS); (2) mixed lymphocyte response (MLC) stimulated by irradiated allogeneic cells; and (3) the induction but not the expression of the cytolytic lymphocyte response. The inhibition does not seem to be due to toxicity but occurs only in the presence of calf or foetal calf sera.

When micromolar quantities of spermine and spermidine

Fig. 1 Effect of polyamines on lymphocyte mitogen responses. 5×10^5 BALB/c spleen cells were cultured in flat bottom Falcon microtest II plates in a volume of 200 μ l in RPMI 1640 medium with 5% FCS which contained nil or a, 0.25 μ g con A (Pharmacia) or b, 1.0 μ g *E. coli* 055:B5 lipopolysaccharide (Difco). The indicated amount of polyamine (obtained from Calbiochem as cadaverine dihydrochloride, putrescine dihydrochloride, spermidine trihydrochloride and spermine tetrahydrochloride dissolved in serum-free medium) was added in 50 μ l making the final volume 250 μ l. Cultures were pulsed with 0.1 μ Ci ^{125} I-IUDR (250 μ Ci μ g⁻¹) (New England Nuclear) after 44 h of culture and cells were collected 18 h later using a multiple automated sample collector (Otto Hiller, Madison, Wisconsin). Samples were counted in a Packard automatic gamma spectrometer. The mean and standard deviations of quadruplicate cultures are shown. Polyamines tested were putrescine ($\text{NH}_2(\text{CH}_2)_4\text{NH}_2$) (×), cadaverine ($\text{NH}_2(\text{CH}_2)_5\text{NH}_2$) (○), spermine ($\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$) (□) and spermidine ($\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}_2$) (△). All cultures which did not contain mitogen (●) but did contain varying concentrations of polyamine gave essentially the same low incorporation rate as shown by this representative plot.

Fig. 2 Serum requirements for spermidine inhibition of mitogen responsiveness. Spleen cells were cultured, additions made, and DNA synthesis measured as described in the legend to Fig. 1, except that the amount of mitogen per culture was 0.5 μ g con A. FCS (▲), calf serum (■) obtained from calves 3–6 months of age, and human serum (○) were present at a final concentration of 4% and mouse serum (●) at 0.4%. Cells cultured in serum-free medium are represented by (□). Essentially identical curves were obtained for PHA, PWM and LPS.

were added to cultured murine spleen cells stimulated with LPS or con A, the DNA synthetic response was inhibited. Identical doses of putrescine and cadaverine had no effect (Fig. 1). Similar results were obtained for PWM and PHA stimulated cultures. Larger doses of polyamine were required to suppress the response to PHA or con A than to suppress that to LPS and PWM. The inhibition could be demonstrated with either calf or foetal calf serum (FCS) in the cultures. In parallel cultures with human or mouse serum, or with no serum, there was no inhibition in spite of the presence of up to 10 μ g per well of spermine and spermidine (Fig. 2).

When FCS was titrated into cultures containing a constant 4% human serum, polyamines inhibited LPS and con A stimulated mitogenesis when the FCS concentration reached 0.5–1.0%. This suggests that some component of FCS is essential for the inhibition.

We next tested whether the observed inhibition was due to toxicity. First we examined the effect of spermine added at different times after inception of standard cultures

stimulated with either con A or LPS. When spermine was added up to 29 h after inception of culture, it could completely inhibit the LPS response. To inhibit the con A completely, spermine had to be added within 22 h of culture inception. The later the polyamine was added, the more was required to obtain the same level of inhibition. This argues against a simple mechanism of acute toxicity but is consistent with an effect on some early event in the differentiation of mitogen-stimulated lymphoid cells.

To investigate the reversibility of the inhibition, we preincubated murine spleen cells (2.5×10^7 in 50 ml of medium RPMI 1640 and a final concentration of 2% FCS with no additions or with spermine ($10 \mu\text{g ml}^{-1}$) or spermidine ($10 \mu\text{g ml}^{-1}$) for either 24, 48 or 72 h. Cultures were then collected, washed three times and subcultured in the microtest II system (see legend of Fig. 1) where they were stimulated with PHA, PWM, con A, or LPS. The responses were compared with those of fresh murine spleen cells obtained each day and cultured in parallel. Control cells, preincubated for 24 h without polyamine, responded well (although less than did fresh cells) to each mitogen when tested in subculture: cells preincubated for 24 h with supra-inhibitory doses of polyamine responded as well as did preincubated control cells in culture.

Cells cultured with and without polyamine for 48 h responded less well to T cell mitogens in general, but there was no significant difference between those preincubated without polyamine and those preincubated in spermidine. By this time, however, all preincubated cells have lost their ability to respond to LPS and PWM and the level of radiolabel incorporation by preincubated cells subcultured without stimulus has increased significantly.

After 3 d of preincubation no cells responded to the mitogens when subcultured. There was no significant difference in the recovery of total viable cells preincubated in spermidine compared to control medium.

The fact that spermine or spermidine at 5–10 μ g per well completely inhibited the response to mitogen when added at the inception of culture (Fig. 1) or 22 h later, but not after preincubation in either polyamine for 24 h suggests that a toxic principle was not responsible for the lack of iododeoxyuridine (IUdR) incorporation in the subcultures. It is consistent with polyamine affecting some event in stimulated cells rather than having a nonspecific deleterious effect on quiescent cells.

Polyamines also inhibit the ability of murine lymphocytes to recognise irradiated allogeneic cells (Table 1). Furthermore, the ability of cells in a mixed lymphocyte culture to

Table 1 Influence of synthetic polyamines on murine mixed lymphocyte and cell-mediated cytotoxicity responses of CBA spleen cells stimulated by irradiated DBA/2 spleen cells

	Spermine added (μ g)	^{125}I -IUdR incorporated (c.p.m.) $\times 10^3$

	5.0		1.8	
	20.0		0	

^{125}I -IUdR incorporation data are means of four replicate cultures ± 1 s.d. Cells were collected from identical prepared cultures on days 4–6 with the peak control response occurring on day 5. Note that as little as 310 ng of spermine significantly suppressed the response while 1.2 μ g or more of spermine completely suppressed the response. Where polyamine was present only during the expression phase of the cytotoxic response the percentage of chromium release was in excess of 45%. Addition of as much as 20 μ g of polyamine to chromated P-815 target cells alone showed only a 1–2% release of chromium indicating that polyamine *per se* is not acutely toxic to cells known for their fragility.

mount a non-complement-dependent cytolytic response is impaired if polyamines are present from the inception of the culture. Polyamines present only during the chromium release phase of culture do not alter the response nor do they increase the spontaneous release of chromium from the target cells.

These results indicate that certain polyamines have a reversible, suppressive effect on *in vitro* parameters of immunity; a finding of interest for several reasons. The inhibitory property of the product of bovine serum-polyamine interaction may explain why there is only limited DNA synthesis or antibody formation in most studies of *in vitro* immune responses. Lymphocytes contain nanomolar quantities of spermine⁴ and in culture they are normally supplemented with bovine serum. In most *in vitro* systems 60–80% of cells die and probably sufficient polyamine could be released into the medium to react with the bovine serum, form the inhibitor and thus render the response self-limiting.

Spermine and spermidine themselves are not inhibitory; they must either be converted into some other active moiety by the bovine serum or alternatively cause the bovine serum to release an unrelated active molecule.

The possibility that the observations described here were due to toxicity was suggested by a report that a specific amine oxidase of ruminant sera can convert spermine or spermidine to aminoaldehydes toxic to cell cultures⁵. Also, Alarcon found acrolein ($\text{CH}_2\text{CH:CHO}$) in mixtures of bovine sera and polyamine, and wondered whether this might account for the toxicity of the mixtures because acrolein is toxic⁶. We do not believe, however, that either possibility applies to our observations. The strongest evidence against toxicity is the finding that cells preincubated for 24–48 h in supra-inhibitory doses of spermidine later responded to mitogen stimulation as well as did cells preincubated in control medium. It seems unlikely that fixatives such as acrolein or aminoaldehyde would reversibly fix the lymphocyte surface.

Cells involved in the immune response seem to be particularly susceptible to polyamines compared with fibroblasts, for example. Polyamines are widely distributed in mammalian tissues⁷. They are also present in very high concentration in foetal and neoplastic tissues; both of which are known to possess specific antigens but still avoid immunological rejection^{1,8,9}. We postulate that the successful subversion of the host immune system in those individuals bearing tumours or outbred foetuses is mediated by polyamine or a polyamine interaction product. It is conceivable that the product of the interaction of polyamine and bovine serum could inhibit immune reactivity in a general way, and thus represent a natural immunoregulatory agent.

Identification of a thymic inhibitor ('chalone') of lymphocyte transformation as a spermine complex

CHALONES are defined as endogenous, tissue-specific but species nonspecific inhibitors of cell proliferation. Their potential use in the control of neoplasia is well recognised^{1–3}. Circumstantial evidence for the existence of a lymphocyte chalone has been produced^{4–8}, but neither its chemical nature nor its molecular weight have been satisfactorily ascertained. During our search for a lymphocyte chalone, an inhibitor of lymphocyte transformation has been reproducibly isolated from porcine thymic tissue. We report here that though the inhibitor was non-dialysable, its active moiety was identified biologically and chemically as spermine, molecular weight only 202. This accords with the formation in thymic extracts of a tightly bound spermine complex. As the complex displayed some tissue specificity it is possible that an unidentified tissue-specific material acts as a carrier for spermine. In relatively crude extracts of tissues it is probable that spermine-elicited inhibition swamps any authentic chalone activity.

Extracts of thymic tissue were prepared and fractionated by the method of Kiger *et al.*⁵. Briefly, ethanol was added (4 °C) to an aqueous thymic extract (fraction TAE) to a concentration of 42% by vol. The soluble portion (fraction T₁) was dialysed (Visking tubing) against distilled water and subjected to ion-exchange separation on DEAE A-50 Sephadex (Pharmacia). A fraction analogous to (F₂–F₆) of Kiger *et al.*⁵ was obtained, and thoroughly dialysed against distilled water. Fractions were freeze-dried for storage at –20 °C. The most highly purified (F₂–F₆) sub-fraction contained a mixture of material with a molecular weight ranging from 50,000 down to 800 as defined by P-60 and P-2 (Biorad) gel filtration.

Table 1 Comparison of inhibitory doses (ID) of thymic extracts and polyamines on PHA-stimulated lymphocyte, fibroblast and granulocyte uptake of ³HTdR (DNA synthesis) in medium containing foetal calf serum

Fraction	Lymphocytes ID ₅₀	Fibroblasts ID ₅₀	Granulocytes ID ₅₀
TAE	275 µg ml ⁻¹	> 1,000 µg ml ⁻¹	> 1,000 µg ml ⁻¹
T ₁	210 µg ml ⁻¹	1,000 µg ml ⁻¹	1,000 µg ml ⁻¹
(F ₂ –F ₆)	100 µg ml ⁻¹	500 µg ml ⁻¹	500 µg ml ⁻¹
(F ₂ –F ₆) polyamines	20 µg ml ⁻¹	20 µg ml ⁻¹	25 µg ml ⁻¹
Spermine	12 µM	12 µM	15 µM
Spermidine	36 µM	36 µM	n.t.
Putrescine	> 160 µM	n.t.	n.t.

Triplicate 1.0 ml cultures of 5 × 10⁶ young male rat (Sprague-Dawley strain) thymic lymphocytes were incubated with 15 µg of purified PHA (Wellcome) in 75 × 10 mm tubes (Falcon) for 62 h, and uptake from 1.0 µCi of ³HTdR (2 Ci mmol⁻¹) or ³HUdR (10.3 Ci mmol⁻¹, Radiochemical Centre) was measured for the last 16 h of incubation. Hamster lung fibroblasts (Yerganian cell line) were established in Leighton tubes (1.0 ml triplicate cultures) and uptake of 1.0 µCi was measured over one generation of cells (16 h). Rat granulocytes were assayed by the method of Paukovits¹⁷. Medium RPMI 1640 (Flow) containing antibiotics, 2 mM L-glutamine, 16 mM NaHCO₃ (buffer) and 12.5% foetal calf serum (Rehatuin, Armour) were used for all cultures. The same batch of serum was used throughout. Completed media containing thymic extracts or polyamine were incubated for 1–2 h before adding cells. Reagents were sterilised by filtration through Millipore 0.22 µm membranes. Cultures were incubated at 37 °C in an atmosphere of 5% CO₂ in air. Results were calculated from a dose-response curve plotted for the mean d.p.m. (background subtracted) of triplicate cultures. Standard deviations were less than 12% of the mean. Relative uptake of ³HUdR was similar to that for ³HTdR and so is not considered in the Table. Measurement of incorporation of radio labels in TCA-precipitable material of washed collected cells in PCS scintillator (Searle) was made using a Beckman spectrophotometer. n.t., Not tested.

Thymic fractions TAE, T₁ and (F₂-F₆) inhibited DNA synthesis (measured by uptake of ³HTdR) and RNA synthesis (uptake of ³HUdR) equally, in phytohaemagglutinin (PHA)-stimulated rat thymic lymphocytes. In contrast, the inhibition was significantly less when assayed against fibroblast or granulocyte proliferation. Representative results are summarised in Table 1. In addition, administration of fraction (F₂-F₆) to CBA recipient mice for full-thickness WH strain mouse tail-skin allografts at a dosage of 7.0 mg per mouse on days -1, 1, 3 and 6 after grafting, produced significant ($P=4.75$ for 12 d.f.) but not dramatic prolongation of graft survival from 10.14 ± 0.28 (s.d.) to 12.86 ± 0.51 d.

Thus the extract (F₂-F₆) was shown to exhibit chalone-like activity both *in vitro* and *in vivo*. A remarkable finding was that all the above fractions completely lost inhibitory activity when instead of foetal calf serum, human serum (adult or foetal-cord) was used to supplement cultures. Results using fraction (F₂-F₆) are shown in Fig. 1. Byrd *et al.*⁹ have reported that potent inhibition of lymphocyte transformation was evoked by the polyamines spermine and spermidine, and that the phenomenon was similarly dependent on the presence of bovine serum. We have observed similar effects and shown fibroblasts and granulocytes to be equally susceptible (Table 1); putrescine was not an inhibitor. Moreover, injection of 1.0-mg doses of spermidine (Sigma) in the schedule described above caused a somewhat longer retention of skin grafts than previously obtained with fraction (F₂-F₆).

Experiments still in progress indicate that the inhibitory properties of the polyamines are closely linked to plasma amine oxidase activity, which is abundant in ruminant sera but shows little activity in human sera. If this is so, the aldehydes produced by the enzymic oxidative deamination of spermine and spermidine must be exceedingly potent inhibitors. Consequently, our investigations were continued to explore the possibility of the thymic fractions containing

Fig. 1 Inhibitory activity of thymic fraction (F₂-F₆) on the uptake of ³HTdR by PHA-transformed lymphocytes in foetal calf serum (●) and absence of activity in human serum (○). Culture details are presented in Table 1. Each point represents the mean d.p.m. of triplicate cultures $\pm$ s.d. (background subtracted).

Fig. 2 Inhibitory activity of polyamine residue separated from thymic fraction (F₂-F₆) on uptake of ³HTdR by PHA-transformed lymphocytes in foetal calf serum (●) and in human serum (○). Culture details are presented in Table 1. Each point represents the mean d.p.m. of triplicate cultures $\pm$ s.d. (background subtracted).

polyamines. Fraction (F₂-F₆) was subjected to the polyamine extraction procedure of Inoue and Mizutani¹⁰. The hydrolysed residue obtained potentially inhibited lymphocyte transformation in foetal calf serum ($ID_{50}=20 \mu\text{g ml}^{-1}$) but not in human serum (Fig. 2). Analysis by gas-liquid chromatography (GLC) of the trifluoroacetylated residue using the method of McGregor *et al.*¹¹ confirmed that the residue contained roughly 20% spermine together with a trace of spermidine. On the basis of its spermine content, the residue had an ID_{50} of about $4.0 \mu\text{g ml}^{-1}$, reasonably close to that of authentic spermine. The loss of apparent tissue specificity on extraction of spermine from fraction (F₂-F₆) suggests that the spermine may exist in (F₂-F₆) as a tightly bound complex, with the carrier conferring the specificity. In addition, since both spermine and spermidine are present in normal tissues¹², the carrier itself showed a preference for spermine.

Finally, a series of experiments using ¹⁴C-spermine tetrahydrochloride were conducted, to study the extent of dialysis of spermine from the thymic fractions and from other materials. The essential finding was that 0.6% to 3.5% of spermine initially present could survive the extraction procedure (full details will be published elsewhere). Available data on polyamine concentrations in tissues¹³ show that this is quite sufficient to account for the amount isolated and identified in this work.

These results emphasise the difficulties associated with the isolation of an authentic lymphocyte chalone, but by no means rule out its existence. Polyamines have been implicated in growth processes¹⁴⁻¹⁶ and increased cellular levels are associated with optimal PHA-induced transformation of lymphocytes¹⁷. The activation of spermine, possibly with an amine oxidase, may thus represent a sensitive physiological control mechanism. The possibility that this mechanism is mediated by a larger, specific carrier molecule is not discounted.

Calcium ion produces graded changes in permeability of membrane channels in cell junction

THE permeability of the membrane channels in *Chironomus* salivary gland cell junction depends on the cytoplasmic Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) (refs 1, 2). At the normal $[\text{Ca}^{2+}]_i$, $< 10^{-7}$ M, the channels are highly permeable to a wide range of molecular sizes; the upper size limit for peptide molecules is about 1,200–1,900 molecular weight (MW) (refs 3,4). When the $[\text{Ca}^{2+}]_i$ is elevated above 5×10^{-5} M in the junctional locale, the permeability falls drastically for all molecular species including the small inorganic ions^{2,5,6}. With elevations ranging up to about 5×10^{-5} M the channel permeability is reduced for the 330-MW fluorescein molecule with little or no detectable reduction of electrical coupling⁷. This suggested the interesting possibility that in this range the permeability change may be selective, that is, the permeability may fall for the larger molecular species but not for the small inorganic molecules carrying the electrical current. An alternative—that a fraction of the junctional channels closed unselectively (that is, completely)—could not be excluded, however, because the sensitivities of the methods for discriminating changes in the junctional permeabilities of the large and small molecular species were not equivalent; the measurements of electrical coupling, while quite sensitive to changes in junctional permeability in the low range of electrical coupling, are relatively insensitive at high levels of coupling⁷. Here we investigate this point by testing junctional permeability with fluorescent molecules of various sizes. In each test we use a pair of molecular species and compare their transit times during simultaneous diffusion in the same direction across the junction. If and only if the non-selective mechanism governs the Ca^{2+} -mediated permeability reduction, the transit for both species should be equally retarded, irrespective of size or structural differences between the probe molecules. We show that, at low $[\text{Ca}^{2+}]_i$

elevation, the junctional permeability reduction is indeed selective and that the molecular size limit for junctional channel permeation changes in a graded manner.

A series of seven water-soluble fluorescent-labelled molecules ranging from 380 to 1,158 MW were used as permeability probes of the junction of *Chironomus* salivary gland cells (mid-fourth instar). These tracer molecules permeate the junctional membrane but not significantly the non-junctional membrane³ and, at the $[\text{Ca}^{2+}]_i$ used, their Ca binding is negligible and their (paper) electrophoretic mobility is unchanged. The tracer molecules were injected into the cells using micropipettes and a pneumatic pressure system². Permeabilities were tested by pair comparisons; each pair of tracers to be studied (Table 1) was injected as a mixture. In every pair, one tracer had a yellow-green fluorescent label of fluorescein isothiocyanate (FITC) or dansyl (DANS), and the other, a red fluorescent label of lissamine rhodamine B (LRB). Thus, the members in the pairs were easily distinguishable in the cells by means of appropriate barrier filters. The concentration ratio for a given pair was approximately constant and the fluorescence intensities were roughly matched. Only changes in transit time are of interest, however, so differences in absolute concentration and in detectability were of no consequence (so long as source concentration $\gg$ threshold for detection). The intracellular and transjunctional spread of the fluorescent tracers was observed and photographed directly in a darkfield microscope and/or scanned and videotaped through an image intensifier-television system². The tracers moved through the cytoplasm and the junction with velocities inversely related to their molecular weights; their arrival at the junction was marked by an abrupt fall in velocity³. Junctional permeabilities were measured as transit time, that is, the interval between the moment the tracer arrives at the junction and the moment it appears in the adjacent cell. Junctional transit speed in elevated $[\text{Ca}^{2+}]_i$ will be given relative to speed in Ca-free controls (determined at the same concentration ratio for a given pair); the relative transit speed (v), then, is defined as the ratio of the mean transit time of controls to transit time in the presence of Ca^{2+} . The experiments were carried out at room temperature, 22–25 °C.

Ca^{2+} buffered with citrate or mixed with ethyleneglycol-bis (β -aminoethyl ether)- N - N' -tetraacetic acid (EGTA) was injected together with the tracers or, in some cases, separately before the tracer injection. The free Ca^{2+} concentration in the injection solutions ranged from 10^{-4} to 10^{-2} M: this concentration had to be so high because Ca^{2+} is rapidly sequestered inside the cells and its concentration falls off precipitously with distance from the injection point. By the time the injected Ca^{2+} reaches the junction, some 50 μm away from our standard injection point (about cell centre), its concentration has fallen several orders of magnitude⁸. With the quantities and rates of the present Ca^{2+} injections, we expect, on the basis of earlier work in which the spatial distribution of $[\text{Ca}^{2+}]_i$ was determined using aequorin², that the $[\text{Ca}^{2+}]_i$ elevations in the junctional locale were in the range of 10^{-7} to 10^{-5} M.

The basic result was that, on elevation of $[\text{Ca}^{2+}]_i$ in this range, the transjunctional flow of the larger molecules was

Table 1 Tracer pairs

Pair no.		Molecular weight		Molecular weight
I	LRB (Leu) ₃ (Glu) ₂ OH	1,158	/DANS (Leu) ₃ (Glu) ₂ OH	849
II	LRB (Leu) ₃ (Glu) ₂ OH	1,158	/FITC (Glu) ₃ OH	794
III	LRB (Leu) ₃ (Glu) ₂ OH	1,158	/DANS (Glu) ₃ OH	640

V	LRB (Gly) ₆ OH	901	/DANS (Glu) OH	380
VI	DANS (Leu) ₃ (Glu) ₂ OH	849	/LRB SO ₃ H	559
VII	FITC (Glu) ₃ OH	794	/LRB SO ₃ H	559

LRB, Lissamine rhodamine B; DANS, dansyl (dimethylamino-naphthalene sulphonyl); FITC, fluorescein isothiocyanate; Glu OH, glutamate; Leu OH, leucine; Gly OH, Glycine.

slowed more than that of the smaller ones and in some cases was even sensibly blocked while the small molecules were passing.

With Ca-free control solutions, containing EGTA or citrate, all seven tracer molecules passed through the junction with transit times ranging from a few seconds to about 1 min, depending on size. The transit times were the same as when EGTA or citrate was omitted³. With Ca-containing solutions the junctional transits were retarded, and in almost every test with pairs *III* to *VII* (Table 1) the retardation of the larger molecule (L) exceeded that of the smaller companion (S). Figure 1 presents the complete data for relative junctional transit speeds (v) of tracer pairs *III*, *IV*, *VI* and *VII*. The plots include also those cases with selective block of one molecule in a pair, invariably the larger ($v_L \approx 0$). Drawn in each graph is the line ($v_L/v_S = 1$) that would represent equal retardation of both tracers, namely non-selective retardation of junctional permeability. Nearly all points fall below the line. Application of the two-sample t test to the aggregate data of each graph, to compare the retarded junctional tracer movement with the control tracer movement, shows clearly that for all four tracer pairs the permeability reduction is selective; the confidence levels for $v_L/v_S < 1$ are 0.5, 5, < 0.5, and < 0.1% respectively for the pairs *III*, *IV*, *VI* and *VII*. A smaller number of experiments with *V* gave the same results; although only 6 trials were made, the confidence level was 3%. No selective junctional permeability reduction was found with the two pairs of the four largest molecules, pairs *I* and *II*; within the resolution of the method, the junctional transits of these molecules were equally retarded by $[Ca^{2+}]_i$ elevation. Eventually, at high $[Ca^{2+}]_i$, all seven molecules were blocked.

A significant feature of the results is the occurrence of selective block of junctional transit of the larger molecule in the pairs giving selective permeability reduction (two examples are

Fig. 1 Selective retardation of junctional transit by Ca^{2+} . Plotted are the relative junctional transit speeds (v) modified by Ca^{2+} for the small (S, abscissae) and large members (L, ordinates) of tracer pairs *III*, *IV*, *VI* and *VII*. Each value of v is the ratio of the mean junctional transit time in Ca-free controls to a single measurement of transit time in elevated $[Ca^{2+}]_i$. The subscripts give the molecular weights of the tracers. Each graph presents all data for a given tracer pair, including those of selective block (circled; $v_L = 0$). Squares denote repeated data points, with the multiplicity indicated. The line represents $v_S = v_L$, that is, equal (non-selective) retardation of junctional transit. The resultant confidence levels for $v_L < v_S$ are (*III*) 0.5, (*IV*) 5, (*VI*) < 0.5 and (*VII*) < 0.1%. (The numbers of controls and two other underlying statistics, the ratios of mean transit times (L/S) of the controls $\pm$ s.e. were: (*III*) 5; 1.29 ± 0.27 ; (*IV*) 8; 2.67 ± 0.58 ; (*VI*) 5; 2.36 ± 0.54 ; (*VII*) 11; 1.18 ± 0.16 , respectively.)

Fig. 2 Selective block of junctional transit. Permeability of junctional membrane channels is probed with pairs of fluorescently-labelled tracers. The fluorescence of one tracer in each pair is yellow-green and the other is red. The pairs are microinjected into a cell (arrow) together with Ca-buffers and the tracer fluorescence is photographed. Each series of photographs gives, from top to bottom, a view of the cells; the intracellular fluorescence of the smaller tracer molecule; that of the larger molecule (set apart by excitation and barrier filters.) The molecular weights on the photographs identify the tracer pairs. *a*, control; both molecules of the pair have passed from cell to cell. *b* and *c*, the molecules are injected together with Ca^{2+} ; passage of the larger molecule is blocked. The Ca-citrate ratios were: *a*, 0; *b*, 0.8; *c*, 1.0; citrate_{total}, 0.03 M. The photographs of the blocked tracers (*b* and *c*) were taken 5 min after those of their respective smaller companions; the interval injection-to-photography was in *b* and *c* 35-fold the control transit time. In *a* the photograph of the larger tracer was taken before that of the smaller tracer; the interval injection-to-photography for the larger tracer was 15-fold the control transit time. Calibration, 100 μ m.

illustrated in Fig. 2). This shows that the molecular weight limit for junctional permeation decreases on $[Ca^{2+}]_i$ elevation, and decreases in a graded fashion. If a stepwise decrease in molecular limit for junctional permeation is assumed, then, with the resolution afforded by the present probe repertoire, one may admit at least one gradation: one between 1,158 and 640 MW (or between 794 and 559). If we extrapolate now to the earlier result showing a dissociation between the junctional passage of the molecule of 330-MW (fluorescein) and electrical coupling, two further steps seem likely: one between 330 MW and the size of the smallest inorganic ion; and a third where even the latter ion is barred from junctional passage as the $[Ca^{2+}]_i$ concentration at the junction rises above about 5×10^{-5} M (refs 2,6). The actual grading may, of course, be finer and charge properties of the molecules may be additional contributing factors.

In seeking a controlling variable for the grading in junctional permeability, one is drawn to $[Ca^{2+}]_i$. Not only is this variable continuous, but at extreme values (10^{-7} M and $\sim 5 \times 10^{-5}$ M) it is associated with the extremes of junctional permeability, and an intermediate range is associated with intermediate permeabilities.

Seen in terms of the idea that the permeable junction is made of unit channels^{4,9-11}, the gradual decrease of the molecular size limit may be attributed to a gradual diminution of effective channel size on $[Ca^{2+}]_i$ elevation. The junction would behave like a sieve in which the unit mesh can be controlled by Ca^{2+} . Alternatively, the junction might contain channels of different size and Ca sensitivity. Here the result would be accounted for by an all-or-none closure of channels with Ca^{2+} sensitivities directly related to channel size.

As to the mechanism whereby Ca^{2+} affects the channels, it is plausible that this ion binds to junctional membrane causing a change in the channel's fixed charge or molecular conformation that reduces its effective size (by a decrease in the size of the membrane channels or by their misalignment on the two

membranes)^{4,7}. There is electron microscopic and spectroscopic evidence for Ca deposits at junctional membranes¹²⁻¹⁴ and for changes in size and packing of membrane particles in 'gap' junction in conditions where $[Ca^{2+}]_i$ is expected to have risen¹⁵.

The graded control of junctional permeability by Ca^{2+} offers in principle a powerful mechanism for physiological regulation of intercellular communication; it provides a means for selective transmission of intercellular molecular signals. A case in point may be in embryonic development where, as proposed earlier¹⁶, selective uncoupling of molecular signals could provide an economical means for producing stable cellular differentiations. In fact, for early embryos, there is evidence that fluorescein may not pass between electrically coupled cells¹⁷⁻¹⁹. If this phenomenon turns out to be due to a truly selective restriction of permeability (rather than due to a non-selective reduction in the number of channels; see above), it will be interesting to see whether the $[Ca^{2+}]_i$ is elevated at this developmental stage.

We thank Dr S. J. Socolar for valuable discussion. This work was supported by the USPHS.

Selective inhibition of thromboxane A_2 biosynthesis in blood platelets

SAMUELSSON'S group^{1,2} showed that human platelets convert arachidonic acid and prostaglandin (PG) endoperoxides³ to thromboxane A_2 (TXA₂). TXA₂ strongly aggregates platelets¹ and contracts vascular strips^{1,4,5}. Vane's group^{5,6} has identified TXA₂ synthetase in platelet microsomes—this enzyme generates TXA₂ from PG endoperoxides. Aspirin-like drugs inhibit generation of PGs (refs 7, 8) and TXA₂ (ref. 9) in platelets at the early stage of cyclooxygenation of arachidonic acid^{10,11}. It is through this activity that aspirin, indomethacin, naproxen and other acidic anti-inflammatory drugs are anti-aggregatory^{11,12}—they have little or no effect on generation of TXA₂ from PG endoperoxides⁶. We report here that the non-acidic anti-inflammatory compound 2-isopropyl-3-nicotinyl-indole (L 8027) (refs 13, 14) is a selective TXA₂ synthetase inhibitor in platelets and a potent anti-aggregatory agent.

The inhibitory effect of L 8027 on the PG synthetase system was evaluated in bovine (BSVM) and ram (RSVM) seminal vesicle microsomal preparations. Fresh BSVM (refs 15, 16) or lyophilised RSVM (ref. 17) (2-3 mg ml⁻¹) were incubated with sodium arachidonate (33 μ M) in 66 mM phosphate buffer pH 8.0 for 5 min at 37 °C or at 30 °C, respectively. The incubation mixture with BSVM also contained glutathione (166 μ M) and hydroquinone (45 μ M). L 8027 (1-40 μ M) was pre-

incubated with the microsomal preparations for 6 min before the substrate was added. The activity of cyclo-oxygenase in RSVM was evaluated by polarographic measurement of the oxygen uptake¹⁸. The activity of PG synthetase system in BSVM and in RSVM was evaluated by bioassay of the PG-like product¹⁶. In BSVM 80-90% of the bioassayed PG-like activity was PGE₂ (ref. 13). The biologically active products which were formed from arachidonic acid by RSVM in the absence of cofactors were not separated by chromatography. The concentrations of L 8027 required to inhibit the enzymic activity by 50% (IC₅₀) were: 5.9 μ M in BSVM, 17 μ M in RSVM (as measured by bioassay) and 13 μ M in RSVM (as measured by oxygen consumption). Thus we found L 8027 to be 60-180 times less potent than indomethacin and 10-30 times more potent than aspirin as a PG synthetase inhibitor. This is in agreement with the data of Deby *et al.*¹³ on the relative anti-PG synthetase potency of L 8027.

TXA₂ synthetase activity in platelet microsomes was evaluated by an indirect method. The PG endoperoxide generating system of RSVM (ref. 3) was coupled⁶ to TXA₂ synthetase of horse platelet microsomes (HPM) (ref. 5). The biological activities of PG endoperoxides and TXA₂ were differentially assayed on a strip of rabbit mesenteric artery which is relaxed by PG endoperoxides and contracted by TXA₂ (ref. 19). Other bioassay organs used were rabbit aortic strip²⁰ and rabbit vena cava¹⁹ (both contracted by TXA₂ and by PG endoperoxides), rat stomach strip²¹ and rat colon²². Rat stomach strip is contracted by PEG₂, PGF_{2 α} , PG endoperoxides and TXA₂ in a decreasing order of potency⁹. Rat colon is not sensitive to TXA₂ and PG endoperoxides (up to 100 ng), but is contracted by PGF_{2 α} and PGE₂. The assay tissues were superfused in cascade²³ with Krebs bicarbonate (3 ml per min, 37 °C), containing a mixture of combined antagonists²⁴ and indomethacin (1 μ g ml⁻¹). In three experiments the concentrations of L 8027 needed for 50% inhibition of TXA₂ synthetase in HPM were 0.25 μ M, 0.3 μ M and 0.8 μ M. Thus L 8027 was 16-52 times more potent as an inhibitor of TXA₂ synthetase in HPM than as inhibitor of cyclooxygenase in RSVM.

In rabbit platelet homogenates L 8027 at concentrations of 0.3-1 μ M also inhibited TXA₂ generation from arachidonic acid (three experiments as in Fig. 1). At the same time L 8027 hardly influenced PG generation by platelet homogenates as shown by contractions of rat colon (Fig. 1).

The most striking inhibitory effect of L 8027 on TXA₂ generation, however, occurred in aggregating platelets. Aggregation of platelets in 1 ml of fresh citrated rabbit platelet-rich plasma (PRP) was monitored in a Chrono-Log aggregometer. Aggregation was induced by sodium arachidonate (AA, 25-200 μ M) or by adenosine diphosphate (ADP, 10 μ M). L 8027 was preincubated with PRP at 37 °C for 6 min before an aggregating agent was added. Sixty seconds later a 100- μ l aliquot of PRP was withdrawn and immediately bioassayed on a strip of rabbit mesenteric artery for TXA₂. In 10 PRP the threshold pro-aggregatory effect of AA (25-70 μ M) was completely abolished by L 8027 at concentrations of 40 pM-10 nM. Anti-aggregatory concentrations of L 8027 mounted up to 0.1-1.0 μ M in parallel to an increase in the pro-aggregatory concentrations of AA (100-200 μ M). These anti-aggregatory concentrations of L 8027 (40 pM to 1 μ M) also dramatically suppressed the release of TXA₂ from platelets by AA. In eight PRP the ADP-induced aggregation was not inhibited by L 8027 at concentrations up to 40 μ M. ADP-induced aggregation was not associated with the detectable release of TXA₂.

The selective inhibition of TXA₂ synthetase by L 8027 in horse platelet microsomes and in rabbit platelet homogenates explains the potent anti-aggregatory effect of L 8027 on rabbit platelets. But, high anti-aggregatory potency of L 8027 against the threshold pro-aggregatory concentrations of arachidonate as well as an instant drop of this potency in parallel to an increase in concentration of the pro-aggregatory agent indicates that anti-TXA₂ synthetase activity of L 8027 is strongly dependent on the substrate concentration. It could be that L

Fig. 1 Bioassay of thromboxane A_2 and prostaglandins generated during an incubation of arachidonic acid (AA) with rabbit platelet homogenate (RPH). Platelets were obtained from 40 ml of rabbit platelet rich plasma and resuspended in 5 ml of 50 mM Tris buffer pH 7.4. The suspension was subjected to thawing and freezing three times and centrifuged at 5000g for 15 min to remove cell debris⁹. 200 μ l of the supernatant (RPH) and 300 μ l of AA (300 μ M) were mixed and kept on ice. After 3 min an aliquot of 100 μ l was bioassayed. In one experiment L 8027 (1 μ M) was preincubated with RPH for 3 min at 22 °C before AA was added. The assay organs (rabbit mesenteric artery, rabbit aorta, rat colon and rat stomach) were calibrated with 15 ng and 7.5 ng of PGE_2 . Presence or absence of each component of the incubation mixture is marked with X or 0, respectively. L 8027 inhibited the generation of TXA_2 by RPH (contractile response of vascular strips were either inverted or suppressed) and had little effect on prostaglandin generation (contractions of rat colon remained substantially not changed).

8027 is a competitive, reversible inhibitor of TXA_2 synthetase and therefore an IC_{50} value is not an appropriate measure for its anti-enzymic activity. In our experiments with platelet microsomes we were not able to quantify the amount of PG endoperoxides in the incubation mixture and to calculate K_i value for L 8027. Inability of L 8027 to inhibit the ADP-induced platelet aggregation is in favour¹¹ of the proposed mechanism of anti-aggregatory action of L 8027.

In summary, in our experimental conditions L 8027 at 1 μ M significantly inhibits the generation of TXA_2 by platelet microsomes, by platelet homogenates and by platelet rich plasma. The same concentration of L 8027 does not influence the formation of PG-like material by BSVM, by RSVM and by platelet homogenates (Fig. 1) or the activity of cyclo-oxygenase in RSVM. In our preliminary experiments L 8027 (1 μ M) did not inhibit the spontaneous formation of prostacyclin (PGX, PGI_2) by the incubated rings of rabbit mesenteric arteries²⁷⁻²⁹. Therefore we conclude that L 8027 at concentrations of 1 μ M and lower is a selective inhibitor of TXA_2 generation in blood platelets.

Aspirin, indomethacin and other acidic cyclo-oxygenase

inhibitors are all being considered as anti-platelet drugs¹², though their pharmacological effects and side effects are of a broad spectrum. We suggest that non-acidic L 8027 which is a potent inhibitor of TXA_2 generation in platelets, can compete with cyclo-oxygenase inhibitors in the treatment of thromboembolic diseases.

We thank the Wellcome Trust for providing equipment, Wellcome Research Laboratories (Beckenham, UK) for RSVM, Dr J. Pike (Upjohn) for prostaglandins and Dr M. Descamps (Labaz) for L 8027.

Effects of PGD_2 on canine renal function

In many tissues, especially the mammalian kidney, prostaglandin D_2 (PGD_2) is a significant product in the metabolism of the bisenoic prostaglandin endoperoxides^{1,2}. PGD_2 was originally reported to have negligible biological activity¹; but, subsequent workers noted that it produces vascular effects in several species^{3,4}. Although the effects in the kidney of the precursor, arachidonic acid, and other prostaglandins (PGs)⁵⁻⁷ have attracted much interest, the effects of PGD_2 have received little attention. Since PGD_2 may be an important product of arachidonate metabolism in the kidney^{8,9}, the renal response to an infusion of PGD_2 in the dog was examined and compared with the response to an infusion of PGE_2 . Whereas both PGs produced an increase in renal blood flow, only PGE_2 caused a diuresis and natriuresis. This suggests that PGD_2 in the kidney is primarily involved in the control of renal haemodynamics, and does not participate in the regulation of fluid and electrolyte excretion.

Table 1 shows the renal effects of the infusion of PGD_2 and PGE_2 . The infusion of either prostaglandin led to a pronounced increase in total renal blood flow (RBF). A marked diuresis and natriuresis accompanied the increase

in RBF produced by the infusion of PGE_2 , but not PGD_2 . The glomerular filtration rate (GFR) was not affected by the infusion of PGE_2 , but there was a significant reduction in this parameter during the infusion of PGD_2 . Both PGs significantly enhanced the levels of plasma renin activity in the renal vein (Table 1). The enhancement of RBF induced by the infusion of PGD_2 was caused by an elevation of blood flow to both the outer and inner cortical regions (Fig. 1). No significant alterations were observed in the contralateral kidney, the mean systemic blood pressure or the heart rate during the infusion of either prostaglandin.

Intrarenal infusion of PGD_2 and PGE_2 produced a similar degree of increase in total RBF. Although intrarenal blood flow during the infusion of PGE_2 was not reported in this study, Chang *et al.*⁷ observed that an intrarenal infusion of PGE_2 in the dog promoted an elevation of blood flow to the outer and inner cortical regions. In two experiments in which intrarenal blood flow was measured, the intrarenal infusion of PGE_2 produced alterations in intrarenal blood flow identical to those cited by Chang and co-workers⁷. The intrarenal infusion of PGD_2 also promoted an enhancement of outer and inner cortical blood flows confirming results obtained by Friesinger *et al.*¹⁰. These changes in intrarenal blood flow are similar to those produced by many vasodilators, but differ from the alterations produced by the infusion of the prostaglandin precursor, sodium arachidonate (unpublished observation of P.M.B. *et al.*). When sodium arachidonate is infused intrarenally there is an elevation of inner cortical blood flow, but no concomitant increase in the blood flow to the outer cortex.

As mentioned, the enhancement of RBF induced by the infusion of PGE_2 was accompanied by a marked diuresis and natriuresis, but infusion of PGD_2 had no effect on fluid and electrolyte excretion rates although it did induce changes in renal haemodynamics similar to those produced

by PGE_2 . Oelz *et al.*¹¹ have reported that intrarenal infusion of PGD_2 produced a natriuresis and diuresis in addition to an enhancement of RBF. (Since their data appeared in abstract form it is difficult at present to provide an explanation for the discrepancy between our work and theirs.) During PGD_2 infusion in the present study there was a reduction in GFR, which could have offset any direct tubular effects of PGD_2 . This is unlikely, however, since in subsequent studies we have found that a lower dose of PGD_2 ($0.04 \mu\text{g}$ per kg body weight per min) which produced effects qualitatively identical to those seen with the higher dose of PGD_2 (namely an increase in RBF without an accompanying diuresis or natriuresis) did not reduce the GFR. The absence of a natriuresis and diuresis during PGD_2 infusion could not have been due to a reduction in the renal perfusion pressure, since there was no change in the mean systemic blood pressure during the infusion of PGD_2 .

It is possible that PGE_2 promoted a diuresis and natriuresis because of a direct tubular inhibition of fluid and electrolyte transport. Several groups have observed that the renal prostaglandin system inhibits the action of vasopressin on the collecting duct^{12,13}, and in addition, in the isolated perfused rabbit cortical collecting tubule PGE_2 has recently been shown to inhibit directly the reabsorption of sodium¹⁴. The finding that PGD_2 did not alter the electrolyte and fluid excretion rates is somewhat unusual, since most renal vasodilators produce a natriuresis and diuresis which accompanies an increase in RBF^{15,16}. One exception to this is secretin, which was found to behave in a similar fashion to PGD_2 when infused into the renal artery¹⁷. It exhibited no effect on electrolyte and fluid excretion rates while increasing RBF, and when administered in low dosage there was no significant change in the GFR.

The infusion of both PGD_2 and PGE_2 led to an elevation

Values for the right kidney are given as the mean $\pm$ the standard error. n, Number of animals; RBF, renal blood flow; V, urinary flow rate; $\text{U}_{\text{Na}}\text{V}$, urinary sodium excretion rate; $\text{C}_{\text{H}_2\text{O}}$, free water clearance rate; GFR, glomerular filtration rate; FE_{Na} , fractional excretion of sodium; RVPRA, renal vein plasma renin activity; * $P < 0.05$. Mean values for RBF and RVPRA were not obtained in all nine animals because of inaccurate flow readings in two and the inability to advance a catheter into the right renal vein for blood collections in two others. Mongrel dogs of either sex were fasted for 18 h before surgery and allowed free access to water. Anaesthesia was induced by intravenous pentobarbital (30 mg per kg body weight). An indwelling polyethylene catheter was inserted into the right femoral artery for monitoring systemic blood pressure and collection of blood samples. A catheter was introduced into the left femoral artery and advanced into the left ventricle for injection of radionuclide labelled microspheres ($15 \pm 5 \mu\text{m}$, New England Nuclear). A catheter was also placed in the left femoral vein and advanced into the right renal vein for collection of renal venous blood. A fourth catheter was introduced into the right femoral vein for the infusion of inulin used, to measure GFR. A suprapubic midline abdominal incision was made and both ureters were cannulated. A right retroperitoneal flank incision was made, and a hydraulic cuff and electromagnetic flowprobe were placed around the renal artery. Renal blood flow was monitored by a sine wave, non-occluding electromagnetic flowmeter (Biotronex Laboratories). The hydraulic cuff was used to establish and verify zero renal blood flow. A 25-gauge needle was inserted into the right renal artery proximal to the flowprobe and hydraulic cuff, and normal saline was infused at 0.5 ml min^{-1} . A period of 1 h was allowed for stabilisation before the commencement of the experiment. The study comprised five periods of 15 min duration each. Three 5-min urine collections were obtained during each period. Midway through each period, arterial samples for inulin, osmolality and sodium measurements and renal vein samples for renin determinations were collected. After the first 15-min control period, either PGD_2 ($0.4\text{--}0.8 \mu\text{g kg}^{-1} \text{min}^{-1}$) or PGE_2 ($0.4 \mu\text{g kg}^{-1} \text{min}^{-1}$), was infused into the renal artery for 15 min. Twenty minutes were allowed for renal function to return to control levels and then a second 15-min control period was begun. A 15-min infusion of either PGD_2 or PGE_2 (whichever had not been used before) immediately followed the second control period. The sequence of infusion of PGD_2 and PGE_2 was varied. A final 15-min control period was initiated 20 min after completion of the second PG period. Three bolus injections of differently labelled radionuclide microspheres (^{85}Sr , ^{141}Ce , ^{51}Cr) were administered immediately following the blood collections in the control period before infusion of PGD_2 , during the infusion of PGD_2 and in the control period immediately following PGD_2 infusion. At the end of the fifth period, the animals were killed and the kidneys were removed, weighed and sectioned according to the method of Slotkoff *et al.*²⁰. The sections were counted for radioactivity, to determine intrarenal blood flow. Renin levels were measured by radioimmunoassay. The level of significance was determined by the paired *t* test.

Fig. 1 The effect of PGD₂ on outer cortical and inner cortical blood flows (5 animals). Values for the right kidney are given as the mean $\pm$ the standard error. Outer cortical blood flow is represented by the solid bars and inner cortical blood flow is represented by the striped bars. * $P < 0.05$.

in renal venous plasma renin activity (PRA). It has been shown in an *in vitro* rabbit kidney preparation that arachidonate and several of the PGs directly stimulate renin release¹⁸. Arachidonic acid has also been shown to promote the *in vivo* release of renin in several species^{3,19}.

This study has shown that unlike PGE₂ and other vasodilators, an intrarenal infusion of PGD₂ alters renal haemodynamics without producing concomitant changes in electrolyte and fluid excretion. An infusion of PGD₂ also seems to stimulate renin release; whether this represents a direct action or is consequent to renal haemodynamics cannot yet be answered.

Elevated serum levels of 1 α , 25-dihydroxycholecalciferol in lactating rats

LACTATION represents a challenge to regulation of calcium metabolism. Because of the high rate of calcium transfer to the milk, the lactating rat consuming a commercial stock diet maintains a reduced serum Ca level¹. The increased need for Ca seems to be met primarily by increased intestinal absorption of Ca (ref. 1). Since vitamin D is important for regulation of Ca metabolism, particularly during lactation², and since the circulating level of the active metabolite 1 α ,25-dihydroxyvitamin D₃ (1 α ,25-(OH)₂D₃) seems to be regulated according to Ca needs³, we determined by radioreceptor binding assay the serum levels of 1 α ,25-(OH)₂D₃ in vitamin D-fed lactating rats. We report here that these levels are two- to fourfold higher than those of non-lactating controls. Rats deprived of vitamin D during lactation fail to show elevated metabolite blood levels and develop marked hypocalcaemia, thus indicating the importance of the elevated blood level of 1 α ,25-(OH)₂D₃ for Ca metabolism during lactation.

1 α ,25-(OH)₂D₃ has been called the hormonal form of the vitamin⁴, because its formation in the kidney⁵ as well as its circulating level is apparently stringently controlled. Evidence for such regulation is the absence of an increase in the blood level of this metabolite in the face of a many-fold increase in the blood level of the precursor, 25-OHD₃, during chronic administration of excess vitamin D (refs 5, 6). Regulation of the blood level of 1 α ,25-(OH)₂D₃ may involve negative feedback of this metabolite on its synthesis in the kidney⁷. Factors that can stimulate renal 1 α -hydroxylation of 25-hydroxyvitamin D₃ (25-OHD₃) and cause an elevation of the 1 α ,25-(OH)₂D₃ level in the blood are hypophosphataemia^{3,8} and increased rate of secretion of parathyroid hormone^{3,8–10}, as well as hypocalcaemia independent of parathyroid hormone³.

Rats with litters of ten 6-d-old pups, and non-lactating females of the same age, were obtained from the Holtzman Company, where they had been maintained on a low vitamin D diet with 27% protein, 1.25–1.7% Ca and a Ca : P ratio of 1.5 : 1. On the seventh day of lactation, the adults were assigned randomly by weight to one of two dietary groups. One group received the basic diet consisting of 78% whole wheat flour, 14% casein, 4% corn oil, 2% Ca- and P-free salt mixture, 1.3% of vitamin D-free vitamin mixture (Nutritional Biochemicals) and 0.8% CaCO₃, with a final Ca and P content of 0.4% (–D diet). The other group received the basic diet to which had been added cholecalciferol (Sigma) at a concentration equal to that of Purina Laboratory Chow (5 IU per g of diet) (+D diet). Initially and at weekly intervals during the experiment, non-fasted adults were bled from the tail or by heart puncture and the adults and their litters were weighed. If the size of a litter fell below seven, the mother and pups were excluded from the experiment.

During a 4-d period (days 9–13) the food intake was measured and faeces were collected to determine the daily intake and rate of net absorption of Ca. Ca in food, faeces and serum was determined in a lanthanum chloride solu-

tion by atomic absorption spectrophotometry with a Perkin-Elmer 305 instrument. Phosphate (as inorganic phosphorus) was determined colorimetrically¹¹. Serum (3–4 ml per rat) was frozen for determination of $1\alpha,25-(\text{OH})_2\text{D}_3$ by a competitive radioreceptor binding assay which utilises the chick intestinal cytosol receptor and its association with chromatin. The $1\alpha,25-(\text{OH})_2\text{D}_3$ was first isolated from the serum as described by Hughes *et al.*³, and assayed according to recent modifications of the binding assay procedure¹². Triplicate assays were carried out on all samples, and the interassay variation was 10–15%. Studies with this assay show that vitamin D-deficient animals have undetectable levels of the hormone⁶ and measured circulating levels correlate with expected physiological modulations during dietary alterations of vitamin D (ref. 6), calcium and phosphate³.

Standard errors were calculated from analyses of variance of the data in each experiment and a one-tailed Student's *t* test was used to test significance of differences between mean values.

Table 1 contains the serum Ca levels on the seventh day, which marked the beginning of the dietary treatment, and the serum Ca, P and $1\alpha,25-(\text{OH})_2\text{D}_3$ levels on the 20th day. The seventh day values show that the lactating rats had significantly lower serum Ca levels than the non-lactating rats (experiments 2 and 3). Table 1 also shows that vitamin D-fed rats that had lactated for 20 d had elevated blood levels of $1\alpha,25-(\text{OH})_2\text{D}_3$. In experiment 2 the $1\alpha,25-(\text{OH})_2\text{D}_3$ blood levels of the lactating rats were over threefold higher than that of the non-lactating rats. The same lactating rats had significantly lower serum Ca and higher serum P levels than the non-lactating rats on the 20th day. When vitamin D was withheld from the diet for 2 weeks, lactating rats in experiments 1 and 2 had significantly lower serum $1\alpha,25-(\text{OH})_2\text{D}_3$ and Ca levels than vitamin D-fed lactating rats. This is in contrast to the vitamin D-deprived non-lactating rats (3) which showed no significant reduction in the serum levels of either $1\alpha,25-(\text{OH})_2\text{D}_3$ or Ca compared to their vitamin D-fed controls (experiment 3). Before the effect of vitamin D-deprivation (that is hypocalcaemia) was apparent in the rats in experiment 3 (days 9–13), intestinal absorption of Ca was 123 ± 2 mg per d or $62 \pm 4\%$ of Ca intake (mean $\pm$ s.e., $n=5$) for the lactating rats and 11 ± 2 mg per day or $15 \pm 3\%$ of Ca intake for the non-lactating rats. In another experiment (not shown) with rats that had been maintained on the +D diet and lactated for at least 3 weeks Ca absorption was comparable with that of the lactating rats in experiment 3, confirming the obser-

vation that calcium absorption is markedly elevated during lactation.

The present data represent the first demonstration of elevated serum levels of $1\alpha,25-(\text{OH})_2\text{D}_3$ during lactation. High levels of this hormone have also been found in young rats^{3,13} (as compared with adults) and in the laying hen in which the Ca needs also are increased¹². The serum $1\alpha,25-(\text{OH})_2\text{D}_3$ levels in the non-lactating rats in the present study are comparable with the levels reported for adult rats¹⁴.

The elevation of the $1\alpha,25-(\text{OH})_2\text{D}_3$ blood level in the vitamin D-fed lactating rats could have been due to the relative hypocalcaemia, which was clearly demonstrated, or to increased secretion of parathyroid hormone, which is a usual consequence of hypocalcaemia. Hypophosphataemia, on the other hand, can be ruled out as a stimulus in these rats since the serum phosphate values for the vitamin D-fed lactating rats were actually higher than those for the non-lactating controls. We should also consider the possibility that factors of importance for maintenance of milk secretion, such as thyroid and adrenal hormones and prolactin, also may contribute to elevation of the $1\alpha,25-(\text{OH})_2\text{D}_3$ blood level. In fact, prolactin injection in chicks has been shown to enhance both the activity of the renal 1α -hydroxylase¹⁵ and the circulating concentration of $1\alpha,25-(\text{OH})_2\text{D}_3$ (ref. 12).

While the present data are consistent with the idea that the elevated blood levels of $1\alpha,25-(\text{OH})_2\text{D}_3$ are essential for the maintenance of an increased rate of intestinal Ca absorption, it remains to be seen if a high rate of absorption also can be maintained in the vitamin D-deficient lactating rats perhaps by an action of parathyroid hormone^{16,17} or prolactin¹⁸ or other factors that may influence Ca absorption. Maintenance of serum Ca is apparently dependent on the elevated serum $1\alpha,25-(\text{OH})_2\text{D}_3$ level during lactation since severe hypocalcaemia ensued in vitamin D-deprived lactating rats that lacked the elevated $1\alpha,25-(\text{OH})_2\text{D}_3$ level. The level of $1\alpha,25-(\text{OH})_2\text{D}_3$ fell rapidly in the latter rats, if it can be assumed that this level was elevated during the first week of lactation before the vitamin D-deprivation. Since such deprivation did not affect this level in non-lactating rats, the present data are consistent with the idea that vitamin D metabolism is altered during lactation. In conclusion, it is suggested that elevation of the blood level of $1\alpha,25-(\text{OH})_2\text{D}_3$ takes place as a result of factors associated with the increased Ca demands of milk secretion, and that the elevated level of $1\alpha,25-(\text{OH})_2\text{D}_3$ is required for efficient regulation of Ca metabolism.

We thank Mrs Catherine Lane for technical assistance

Table 1 Serum calcium, phosphate and $1\alpha,25-(\text{OH})_2\text{D}_3$ levels in lactating and non-lactating rats

The +D diet contained 5 IU D₃ per g diet and both +D and −D diets contained 0.4% Ca and 0.4% P. Non-lactating rats in experiment 2 were obtained as such from the supplier, while for experiment 3 rats were rendered non-lactating by removing their pups on the 8th day of lactation. The weight ranges for lactating and non-lactating rats were 240–390 g and 313–426 g, respectively. The mean weights for groups of rats within an experiment were not significantly different from each other ($P > 0.05$), neither were the weight gains by litters from −D and +D mothers. Each Ca and P value is the mean $\pm$ s.e. of 7–11 rats. Each $1\alpha,25-(\text{OH})_2\text{D}_3$ value is the mean $\pm$ s.e. of three or four pools of blood, each from three rats (except for lactating −D rats in experiment 1, two pools from five rats); determinations were in triplicate.

*Different from initial (as paired differences) and from lactating +D where appropriate, $P < 0.01$.

†Different from non-lactating, $P < 0.01$.

‡Different from non-lactating, $P < 0.001$.

§Different from lactating −D, $P < 0.025$.

In vitro induction of binding sites for hCG in rat granulosa cells by FSH

THE granulosa cells (GC) of the Graafian follicle are considered to be the target of the cyclic surge of luteinising hormone (LH) which initiates ovulation and subsequent luteinisation of the follicle. It has been demonstrated that GC acquire receptors for LH during the final stages of follicular growth^{1,2}. In the immature hypophysectomised rat, treatment with oestrogen stimulates GC proliferation and growth of a large number of pre-antral follicles^{3,4}. Cells from these follicles are endowed with follicle-stimulating hormone (FSH) receptors⁵ and respond to FSH with increased progesterin production⁶. They contain few or no LH receptors, however, as reflected by their negligible ability to bind ¹²⁵I-hCG (ref. 7) or to respond to LH with increased progesterin production in culture (G. F. Erickson and A.N., unpublished). A dramatic increase of ¹²⁵I-hCG binding was demonstrated in GC following sequential treatment of immature hypophysectomised rats with oestradiol-17 β and FSH (refs 7, 8). To clarify the cellular mechanism of the induction of the LH receptors, we examined the induction of LH receptors by FSH *in vitro* and show that hCG binding sites can be induced by FSH in GC of pre-antral follicles in cultures of ovarian fragments, but not in isolated GC cultured as monolayers.

Wistar-derived immature hypophysectomised rats (28–30 d old) were each given four daily subcutaneous injections of 0.5 mg diethylstilboestrol in peanut oil (Hx-DES rats) and on day 5, the ovaries were excised aseptically. For organ culture, each ovary was sectioned into 8–12 fragments and these were placed on the grid of a Falcon organ culture dish and incubated⁹. For cell cultures, GC were isolated by puncture of follicles and gentle expression into the medium

and then grown as described by Nimrod and Lindner⁹. The following substances were added where indicated: hFSH (0.1 or 0.5 μ g ml⁻¹, LER-1801-3); androstenedione (0.1 μ g ml⁻¹); oestradiol-17 β (1.0 μ g ml⁻¹); insulin (5.0 μ g ml⁻¹, Squibb); and 8-bromo cyclic AMP (1.0 mM). When the culture period exceeded 48 h, the medium was changed with fresh addition of hormone. At the end of the culture period, the medium was removed and GC were collected using a rubber scraper (cell cultures) or collected from the ovarian segments as described above (organ cultures), and placed in buffered sucrose solution⁵. The cells were sedimented by centrifugation (500g for 8 min) and resuspended in a small volume of buffer by repeated passage through a Pasteur pipette. Highly purified hCG (13,600 U mg⁻¹, Serono, Italy) was labelled with ¹²⁵I (20–50 μ Ci per μ g hCG) by the lactoperoxidase method of Miyachi *et al.*¹⁰ and used in the assay of hCG binding⁵. Briefly, cell suspensions (50 μ l containing 2×10^5 to 5×10^5 cells) were incubated for 3 h at 37 °C in a shaking incubator together with 50 μ l of buffer containing 7–11 ng ml⁻¹ ¹²⁵I-hCG with or without an excess of unlabelled hCG (Pregnyl, Organon; 0.5 U per sample). The difference between radioactivity bound to the cells in the presence and absence of unlabelled hormone was taken to represent specific binding. Progesterone and 20 α -dihydroprogesterone accumulation in the culture medium was determined by radioimmunoassay using specific antibodies¹¹.

Specific binding of ¹²⁵I-hCG to the cultured cells (48 h) was very low (0.16 fmol per 10⁶ cells) even compared with that obtained with freshly collected cells (0.39 fmol per 10⁶ cells). Culture of these cells with FSH, or with FSH in combination with androstenedione, oestradiol-17 β or insulin, had no effect on ¹²⁵I-hCG binding, although the cells clearly responded to FSH with an increased release of progestins into the medium and androstenedione augmented this effect as previously reported⁶.

By contrast, exposure of ovarian fragments in organ culture to FSH (0.1–0.5 μ g ml⁻¹) for 48 h greatly augmented specific binding of ¹²⁵I-hCG to GC (1.19 $\pm$ 0.14 fmol per 10⁶ cells, mean $\pm$ s.e.m., $n=20$, compared with 0.26 $\pm$ 0.03, $n=22$ in untreated controls, $P<0.001$ by Student's t test; compare Table 1). Extension of the culture with FSH to 96 h resulted in a further increase in the number of ¹²⁵I-hCG binding sites (Fig. 1). Addition of androstenedione (Table 1)

Fig. 1 *In vitro* induction of hCG binding sites by FSH in GC during organ culture of ovaries from Hx-DES rats. Time course of increase in binding sites; $\blacktriangle$, FSH-treated (0.5 μ g ml⁻¹); $\bullet$, no hormone supplementation. Vertical bars, $\pm$ s.e.m. ($n=3$).

Table 1 The effect of FSH, androstenedione (Ad) and 8-bromo cyclic AMP on ^{125}I -hCG binding to the granulosa cells in organ cultures of ovaries from oestrogen-treated immature hypophysectomised rats.

Experiment no.	Culture conditions (48 h)	^{125}I -hCG binding (fmol per 10^6 cells)	n
1	No hormones	0.18 ± 0.03	5
	FSH ($0.1 \mu\text{g ml}^{-1}$)	1.23 ± 0.30	3
	FSH + Ad ($1 \mu\text{g ml}^{-1}$)	1.03; 1.47	2
2	No hormones	0.24 ± 0.05	5
	FSH ($0.1 \mu\text{g ml}^{-1}$)	1.17 ± 0.46	5
3	No hormones	0.45 ± 0.07	4
	FSH ($0.5 \mu\text{g ml}^{-1}$)	1.15 ± 0.27	4
4	No hormones	0.19 ± 0.04	4
	FSH ($0.5 \mu\text{g ml}^{-1}$)	1.12 ± 0.29	4
5	No hormones	0.26 ± 0.06	4
	FSH ($0.5 \mu\text{g ml}^{-1}$)	1.31 ± 0.23	4
	8-Bromo cyclic AMP (1.0 mM)	0.25 ± 0.08	4

Uptake by GC pooled from segments of two ovaries was determined in triplicate. Values shown are the mean $\pm$ s.e.m. of values obtained from n replicate cell pools or individual values where $n < 3$.

or oestradiol-17 β (data not shown) together with FSH did not modify the FSH effect. Culture of ovarian segments with 8-bromo cyclic AMP failed to induce hCG binding.

Organ cultures of ovarian fragments produced appreciable amounts of progestins (progesterone plus 20 α -dihydroprogesterone, 140 ± 26 ng per dish per 48 h; mean $\pm$ s.d.), but in contrast to isolated GC cultures, failed to respond consistently to FSH with increased progestin production, whether or not androstenedione or oestradiol-17 β were also added. 8-Bromo cyclic AMP likewise failed to stimulate progestin production in the organ cultures.

The present study represents the first demonstration of an *in vitro* induction of LH receptors in ovarian cells. The failure of 9-bromo cyclic AMP to mimic this FSH effect could signify either that this particular response is not mediated by the adenylate cyclase system, or that penetration of the follicle cells by the nucleotide was inadequate. The low level of ^{125}I -hCG binding in GC of Hx-DES rats offers an advantage over GC from mature follicles in that it eliminates the problem of loss of initial receptor sites during culture. Previously published data on stimulation of hCG binding in porcine GC cultures by FSH (ref. 12) could be interpreted as a reflection of better maintenance of pre-formed receptors, rather than the induction of new binding sites in the presence of this hormone. We were unable to induce the appearance of new receptor sites for hCG by isolated GC after culture with FSH, although the isolated cells responded to FSH with increased progestin production. The difference in the behaviour of GC when cultured alone or in intact follicles suggests the participation of other cellular components of the ovary, or their products, in the induction of the LH receptor by FSH.

This work has been supported by a grant to H.R.L. of the Ford Foundation and the Population Council, New York. We thank Mrs Genia Acevedo, Mrs Ada Tsafiri and Mrs Malka Schattner for technical assistance. LER-1801-3 was supplied by the NIAMDD through Dr L. E. Reichert.

Morphological and biochemical heterogeneity of cholinergic synaptic vesicles

We present findings which seem to show that in an innervated perfused electric organ preparation from *Torpedo* the uptake of freshly synthesised acetylcholine by synaptic vesicles is linked to the discharge of previously stored transmitter by means of at least one cycle of exo- and endocytosis.

The electromotor synapse of *Torpedo* has provided a valuable model system for investigating the molecular basis of cholinergic transmitter storage and release¹. Although the numerous synaptic vesicles present in the nerve terminals seem to constitute a static and homogeneous population when the unstimulated tissue is viewed in the electron microscope, there is evidence that they are, in fact, morphologically and biochemically labile and heterogeneous. Thus, stimulation *in vivo* for short periods at 5 Hz caused marked vesicle depletion and reduction in size² and vesicles isolated from stimulated organs by submitting cytoplasmic extracts to density gradient centrifuging in a zonal rotor had less acetylcholine (ACh) and lower ACh/ATP ratios than those from unstimulated organs^{3,4}. On recovery from stimulation⁵, these changes are reversed, but vesicle numbers and diameters are more rapidly restored than vesicular ACh or ATP. The different types of vesicle do not differ sufficiently in physical properties to be sharply separated on a density gradient, though ACh/ATP ratios are observed to vary across the zonal vesicle peak⁴.

We aimed to modify the buoyant density of vesicles that had undergone exo- and endocytosis by incorporating into them dense material from the extracellular fluid. Sucrose, a constituent of a recently described *Torpedo* Ringer solution⁶, proved suitable for this purpose.

Innervated blocks of electric tissue 20–50 g in weight and comprising the territory of a single nerve were perfused with a physiological saline of osmolality made equal to that of elasmobranch tissue by the inclusion of sucrose (200 mM) and urea (400 mM) (ref. 6). The blocks were cannulated via the blood vessels which accompany the nerves and supply the same territory. Blocks were stimulated via the nerve either moist, in air, or submerged in the perfusion medium; no significant differences were observed with the two methods. The response of the organ was monitored by electrodes placed on its ventral and dorsal surfaces. Whole tissue samples were taken for electron microscopy and vesicles were isolated from cytoplasmic extracts of the blocks on zonal density gradients essentially as described before^{2,5,8}.

To avoid vesicle depletion due to repetitive stimulation we used a low stimulation frequency (0.1 Hz) at which the response of the tissue blocks decayed to about 20–30% of the initial response (27 V) after 1,800 stimuli and the total tissue ACh fell less, to about 30–40% of its initial value (of $1,300 \text{ nmol g}^{-1} \pm 367 \text{ s.e.m.}$, $n=3$). Vesicle numbers (per μm^2 of presynaptic terminal cross section) were not reduced; rather there was a small (up to 50%) increase which might have been caused by volume changes in the terminals during perfusion. There was, however, the same progressive appearance in whole tissue sections of a second population of vesicles about 25% smaller in diameter than the initial population, as occurred at 5 Hz.

When dextran (molecular weight 10,000, 6–10%) was added to the perfusion fluid, few or no dextran particles

were taken up into the vesicles during an initial 3 h perfusion period. When stimulation at 0.1 Hz was applied, however, there was a progressive uptake, mainly into the population of small vesicles (Fig. 1a). After 1,800 impulses, 80% of all vesicles (four experiments) were found to belong to the small diameter population and of these 91% contained dextran. Thus, transmitter release is accompanied by vesicle exo- and endocytosis.

To determine whether vesicles undergoing cycles of exo- and endocytosis were capable of taking up transmitter, ^3H -acetate (sodium salt; $0.5\text{--}1.5\ \mu\text{Ci ml}^{-1}$, $5\ \mu\text{M}$), a precursor of tissue ACh (ref. 7), was added to the perfusion medium; the vesicles were isolated⁸ and vesicular ACh was extracted for assay and separated from unesterified acetate for

Fig. 1 *a*, Effect of stimulation (at 0.1 Hz) on synaptic vesicle profile diameters and the uptake of dextran into synaptic vesicles. The diagrams are normalised distributions of profile diameters in (continuous lines) unstimulated blocks and (dashed lines) blocks stimulated with 1800 pulses. Black blocks show the proportion of profiles of a given diameter that had a dextran particle in the lumen. Numbers in brackets give the number of vesicles measured. Only the small vesicles generated by stimulation contain dextran. *b*, Similar normalised distributions of vesicle profile diameters in vesicles isolated after 1,800 pulses. Note that fraction VP₁ (Fig. 2b) contains only the larger vesicle population whereas the smaller vesicles are recovered in VP₂. Electron-dense granules are restricted to the vesicles in VP₂ and the distribution of profile diameters in this vesicle fraction is similar to that of the newly formed small vesicle population shown in *a*. Abscissa: arbitrary scale.

Fig. 2 *a*, Separation, in a zonal density gradient, of components of a cytoplasmic extract of an unstimulated tissue block showing peak (VP) of vesicular ACh, coincident peak and (arrow) shoulder of ³H-ACh. *b*, Result of stimulation, showing two peaks of vesicular ACh, VP₁ corresponding to, but smaller than VP in (a) and VP₂ corresponding to the shoulder in (a) at the inflexion of the sucrose gradient. Peak VP₂ is highly labelled and does not coincide with the peak of entrapped cytoplasm indicated by lactate dehydrogenase (LDH) (*).

counting by liquid ion-exchange partition⁹. Whereas there was some incorporation of radioactivity into the single peak of endogenous vesicular ACh derived from unstimulated blocks (VP, Fig. 2a), stimulation caused the appearance, in a denser region of the gradient, of a second highly radioactive peak of ACh (VP₂, Fig. 2b) containing about 20% of the total vesicular ACh coincident in position with a shoulder of radioactive ACh observed with the material from control blocks (arrow, Fig. 2a). Meanwhile the height of the peak (VP₁) corresponding to VP was reduced.

The specific radioactivity of the ACh of VP₂ was 16.6 ± 4.8 s.e.m. ($n=5$) times greater than that of VP₁ and 9.2 ± 2.4 ($n=4$) times than that of the parent cytoplasmic extract. Furthermore the ACh of the parent cytoplasmic extract had a specific radioactivity twice that of the tissue ACh (1.9 ± 0.1 , $n=7$). Similar results have been obtained with radioactive choline (J. Suszkiw and H.Z., unpublished) and the incorporation is blocked by hemicholinium-3.

Since the region of the gradient occupied by VP₂ overlaps the rising portion of a peak of membrane fragments, the possibility exists that VP₂ consists of cytoplasmic ACh sequestered within membrane bound particles. That this is

An exciting new journal for all plant physiologists
beginning publication in 1978

Plant, Cell and Environment

Plant, Cell and Environment is a new European journal devoted to the publication of original research reports and theoretical articles in all areas of plant physiology. The objectives of the editors are to combine quality and flexibility of presentation, with rapidity of publication. The coverage includes fundamental and applied aspects of plant cell physiology, plant biochemistry, whole plant physiology, environmental physiology, crop physiology and physiological ecology, together with genetical, structural and pathological aspects as related to function. Contributions of varying character are accepted, including full length papers, short papers for extra-rapid publication, commissioned and submitted 'mini-reviews' on controversial topics and occasional longer reviews, articles on technical advances, annual progress reports commissioned by the Section Editors, book reviews and correspondence columns.

Plant, Cell and Environment publishes only first-quality material, and standards are maintained by a distinguished Review Board, the members of which are the sole referees. To achieve a balance between the various areas of plant physiology the journal is divided into three major sections, each with its own Section Editor, responsible, through the Editor, for the quality and scope of papers published.

Plant, Cell and Environment will be published from March, 1978. Copies will be delivered to North America by air freight and subscribers there can expect to receive their copies within two weeks of British publication.

Editor: Professor Harry Smith, University of Nottingham

Assistant Editor: Dr. E. Ellen Billett, University of Nottingham

Section Editors

Cell Physiology and Biochemistry:
Dr. J.A. Raven, University of Dundee

Whole Plant Physiology:
Professor D.H. Jennings, University of Liverpool

Community Physiology:
Professor P.G. Jarvis, University of Edinburgh

Instructions to Contributors: *Plant, Cell and Environment* has been planned so that papers submitted for publication receive immediate editorial consideration and suitable material is passed to the publishers without delay. Manuscripts should be typed with double-spacing on one side of the paper only and sent in triplicate, together with the illustrations to Professor H. Smith, Department of Physiology and Environmental Studies, School of Agriculture, University of Nottingham, Sutton Bonington, Loughborough LE12 5RD. More detailed advice on the preparation of a contribution may be obtained from the Editor.

Active 'tissue' paper

Our standards for sample oxidisers are difficult to beat.

They are the only standards that are designed to simulate the burning characteristics of cellulose. On combustion they produce an activity that's guaranteed.

Available as ^{14}C or ^3H they add to the excellent range of certified standards we produce.

Internal standards and sets of Unquenched and Quenched standards are all available from stock.

not so was shown by its lack of coincidence with small peaks of the cytoplasmic markers lactate dehydrogenase (Fig. 2b) and choline acetyltransferase, and with a peak of separately prepared synaptosomes ('T-sacs')¹⁰ labelled with ¹⁴C-ACh and added to the cytoplasmic extract from stimulated tissue blocks (Fig. 3). There is good reason to assign the ACh of VP₂ to the population of small vesicles found mixed with membrane fragments in this region of the gradient. When dextran as well as ³H-acetate was perfused through stimulated tissue blocks, those vesicles could be readily distinguished electron microscopically from the larger membrane fragments by their content in electron-dense particles and Fig. 1b demonstrates that the diameter distribution of VP₁ and VP₂ is essentially the same as that between the large and small vesicle populations of intact terminals (Fig. 1a). Furthermore, electron-dense granules can be found only in the small vesicle population. The presence of dextran in the perfusion medium is not, however, essential for the separation of the two populations of vesicles; the essential component is sucrose.

Fig. 3 Separation, in a zonal density gradient, of components of a cytoplasmic extract of a stimulated block to which a preparation of synaptosomes ('T-sacs') labelled with ¹⁴C-ACh, had been added. Note that VP₂ is well separated from the synaptosome peak (Syn) identified by its content of ¹⁴C-ACh and choline acetyltransferase (CAT).

These results seem to show (1) that *Torpedo* electromotor synaptic vesicles, like brain cortex vesicles¹¹, are metabolically heterogeneous with respect to ACh uptake. (2) That the subpopulation of vesicles taking up newly synthesised ACh has undergone at least one cycle of exo/endocytosis. And (3), that such vesicles can be separated from the main population by an artificially induced alteration of density, a technique similar to that used¹² to separate liver lysosomes from mitochondria. The implications of these findings for the vesicle theory of transmitter storage and release¹³ are now being examined.

Interference by bromodeoxyuridine with differentiation in a prokaryote

ENDOSPORE formation in bacteria can be regarded as a primitive form of cellular differentiation as the mature spore has many features, both structural and biochemical, which distinguish it clearly from the growing cell. The extent to which bacterial sporulation can be used as a simple model for development in higher organisms depends on the similarity or otherwise of the control processes which influence cellular differentiation in both cases. It would thus seem important to draw as close an analogy as possible between prokaryotic and eukaryotic differentiating systems. With this in mind, the effect of 5-bromo-2'-deoxyuridine (BUdR) on growth and sporulation in *Bacillus subtilis* has been investigated. When incorporated into the DNA of eukaryotic cells, BUdR (an analogue of thymidine, TdR) selectively affects processes associated with differentiated and embryogenesis, without significantly altering cell growth or gross RNA and protein synthesis^{1–3}. The effects seem best explained by an alteration in transcription^{2,4,5}, possibly caused by tighter binding of chromosomal proteins^{6–8}. This may also be true for prokaryotes, because purified *lac* repressor and catabolite gene activator protein from *E. coli* bind more tightly to BUdR-substituted DNA⁹. Sporulation in *B. subtilis* is controlled to a considerable extent by sequential activation of genes, many of which remain repressed during vegetative growth (for review see ref. 9). We report here that BUdR, at a concentration which leaves growth unaffected, markedly reduces the capacity of *B. subtilis* to sporulate. This effect is comparable with the known interference of this analogue with cellular differentiation in eukaryotes.

B. subtilis 168 (*thy*[−]*A*, *trpC2*) was used as the parent strain, but even partial replacement of the necessary TdR in the medium by BUdR inhibited growth. To overcome this problem a mutant was isolated which still retained the original *thy*[−]*A* mutation, but was much less susceptible to the toxic effects of BUdR. This BUdR-tolerant strain (BUt-32) was able to grow normally (doubling time 36 min) in a rich casein hydrolysate (CH) medium¹⁰ with a BUdR:TdR ratio of 7.5 μg ml^{−1}:1.0 μg ml^{−1}. At higher ratios the growth rate was progressively affected. BUt-32 was selected by a procedure similar to that described for the isolation of 5-bromouracil (BU)-tolerant mutants of *B. subtilis*¹¹. Like the BU-tolerant strains, BUt-32 was unable to grow for more than a few generations with BUdR alone, and a small amount of the natural nucleoside had to be present during growth and sporulation. The basis of the increased resistance to analogue toxicity has not been investigated in either case.

The buoyant density in CsCl of DNA prepared from BUt-32 cells grown with TdR alone was compared with that from cells grown with BUdR and TdR (7.5:1.0). The degree of BUdR substitution can be estimated from the difference in buoyant density between poly d(A-T) and poly d(A-BU) which is 200 mg ml^{−1} (ref. 12). Because *B. subtilis* 168 DNA contains only 28% TdR residues¹³ compared with 50% in poly d(A-T), complete BUdR substitution should give a density increase of about 112 mg ml^{−1}. The density difference found averaged 35 mg ml^{−1} and in separate experiments varied between 40 and 28 mg ml^{−1}. This represents an average 30% substitution by BUdR, a value compatible with earlier results which showed a marked preferential

Table 1 Occurrence of sporulation events in cells supplemented with TdR plus BUdR or TdR alone

Growth and resuspension of cells in media containing*	Exoprotease† (U ml ⁻¹ of culture)	Alkaline phosphatase† (U ml ⁻¹ of culture)	Viable count‡ (colonies per ml × 10 ⁻⁵)	Heat resistance‡ (colonies per ml × 10 ⁻⁵)
TdR (8.5 µg ml ⁻¹)	0.08	0.21	4,030	818
TdR (1 µg ml ⁻¹) + BUdR (7.5 µg ml ⁻¹)	0.14	0.25	3,590	9

*Cells of BUt-32 growing exponentially in rich CH medium were resuspended in a poor minimal salts medium to initiate sporulation¹⁰. Samples of the cultures were assayed at hourly intervals for exoprotease activity¹⁵ and alkaline phosphatase activity¹⁶. Viable count was determined by dilution and plating on nutrient agar. Heat-resistance was determined in the same way, after heating a cell sample at 85 °C for 15 min. The values shown are the results of a typical experiment.

†Maximum values obtained, 4 h and 6 h after resuspension for exoprotease and alkaline phosphatase respectively. 1 unit of enzyme activity is defined as a change in absorption of 0.1 min⁻¹ at 595 nm and 410 nm for exoprotease and alkaline phosphatase respectively.

‡Measured 8 h after resuspension of cells.

uptake and incorporation by *B. subtilis* of the natural nucleoside, TdR, over BUdR^{11,14}.

The effect of this degree of substitution on the ability of the cells to sporulate was investigated (Table 1). During sporulation two early biochemical marker events, exoprotease (Pr) activity and alkaline phosphatase (AP) activity, were assayed and heat-resistance was used as a measure of the number of mature spores formed. The presence of BUdR had the effect of markedly increasing the activities of both Pr and AP over the control values, but the final yield of mature spores was reduced to about 1% of that of the control culture. The low degree of sporulation was not due to loss of viability by the cells incorporating BUdR (Table 1) or to delayed sporulation, for prolonged incubation (24 h) failed to increase the percentage spore yield relative to the control. Prevention of DNA replication is known to prevent sporulation^{17,18}, but DNA synthesis, measured by uptake of ¹⁴C-TdR into acid-insoluble material, continued in a similar manner in both cultures for 2 h after initiation to sporulation (results not shown).

Examination of cells by electron microscopy 7 h after initiation, when the bulk of the control cells had formed readily identifiable spores, showed that BUdR incorporation prevented most cells from reaching the stage of spore septum formation (stage II). Most of the cells incorporating BUdR were normal in length and had nuclear material in the form of an axial filament. Rarely, cells were seen with wall protrusions or 'spikes' at one pole (a recognised stage preceding spore septum formation¹⁹), but generally the cells had no characteristics of sporulating cells. The occasional elongated cell or multiseptate cell was also observed.

This apparent interference by BUdR with an early stage of sporulation was confirmed by exposure of cells grown with TdR alone to BUdR at intervals after initiation to sporulation (Table 2). Cells initiated in the presence of the analogue had a markedly reduced capacity to form spores, only slightly better than that exhibited by cells grown as well as sporulated with BUdR. Initiation of cells in resuspension medium with TdR alone followed by transfer to resuspension medium containing BUdR 1 h after initiation gave a much increased spore yield. By 2 h after initiation in TdR medium exposure of cells to BUdR had essentially no effect on subsequent sporulation. Conversely, cells grown with BUdR, but initiated to sporulation in its absence exhibited a much increased capacity to sporulate, roughly about half that of control cells previously grown with TdR alone (Table 2). This indicated that BUdR incorporation during growth had little subsequent effect on sporulation if initiation occurred in the absence of the analogue. Initiation in the presence of BUdR followed by transfer of cells to a medium containing TdR alone 1, 2 or 3 h later produced a much reduced spore yield when assayed at 8 h, but by 24 h the level of sporulation had recovered almost to that found in control cells. This recovery indicated that the inhibitory effect of BUdR on

sporulation was reversible on removal of the analogue followed by continued incubation in the presence of TdR alone.

Sporulation was induced in these experiments in shift-down conditions involving transfer of cells from a rich to a poor medium. This would have necessitated the general derepression of many genes involved in biosynthetic processes. If BUdR incorporation was affecting transcription generally, the effect on sporulation might be caused, for example, by lack of transcription for a required amino acid rather than an effect on sporulation itself. This explanation seems unlikely for two reasons. First, BUt-32 grew normally (doubling time 65 min) in the minimal resuspension medium supplemented with glucose (0.2%) with a BUdR: TdR ratio of 7.5 µg ml⁻¹: 1.0 µg ml⁻¹. After 24 h only the occasional spore was detected in this medium, yet more than 50% of the cells in a culture grown in the same medium with TdR alone sporulated. Second, when L-histidine (500 µg ml⁻¹) was included in the normal resuspension medium in an experiment similar to that described in Table 1, the rate of synthesis of the inducible enzyme histidase was the same whether the cells had incorporated BUdR or not.

The precise nature of the sporulation-associated events affected by BUdR incorporation is unknown, but certain

Table 2 Effect on spore yield of removal or addition of BUdR at intervals after initiation of cells to sporulation

Time of removal of cell sample after resuspension* (h)	Spore yield†			
	Removal from TdR to TdR + BUdR medium		Removal from TdR + BUdR to TdR medium	
	8 h	24 h	8 h	24 h
0	37	87	280	390
1	310	630	24	420
2	580	1020	13	380
3	710	1040	16	420

*Parallel cultures (50 ml) of BUt-32 were grown in CH medium in the presence of either TdR (1 µg ml⁻¹) + BUdR (7.5 µg ml⁻¹) or TdR (8.5 µg ml⁻¹). To initiate sporulation 10-ml and 40-ml portions of each culture were centrifuged and resuspended in minimal salts medium. For cells grown in the presence of TdR alone the 40-ml portion was resuspended with TdR (8.5 µg ml⁻¹) and the 10-ml portion with TdR (1 µg ml⁻¹) + BUdR (7.5 µg ml⁻¹); the latter represented a time zero transfer to the new medium. Cells grown with TdR + BUdR were treated in a similar manner except that the 40 ml portion was resuspended with TdR + BUdR and the 10 ml portion with TdR only. At hourly intervals for the next 3 h further 10-ml samples were removed from each 40 ml culture, the cells collected on a membrane filter and then resuspended in 10 ml pre-warmed salts medium such that cells previously exposed to TdR alone were introduced into TdR + BUdR medium and vice versa.

†Heat-resistant colonies per ml × 10⁻⁵ determined 8 h and 24 h after resuspension as described in the legend to Table 1. Values for control cultures were 620 (8 h) and 1,130 (24 h) for cells grown and sporulated in the presence of TdR alone and 14 (8 h) and 41 (24 h) for cells grown and sporulated in the presence of TdR + BUdR.

observations deserve comment. The increase in AP activity during sporulation is normally associated with stage II (ref. 21), but BUdR incorporation allowed the increase in activity without the accompanying morphological changes. In addition, both Pr and AP activities were markedly increased over control values. This overproduction of enzyme activity is reminiscent of that seen in certain *spo* mutants⁹ and has also been observed during BUdR incorporation in eukaryotes (noted in refs 7 and 8). The inhibitory effect of BUdR on sporulation only occurred within an initial 2 h after initiation, when DNA replication was in progress, and the effect was reversible on removal of the analogue. Sensitivity to BUdR during a restricted interval of development and reversibility of its effects by further rounds of DNA replication in its absence have been observed in many eukaryotic systems^{1,2}. The presence of BUdR during the growth phase of the cells before the induction of sporulation had only a marginal effect on their subsequent sporulation capacity. This raised the possibility that BUdR inhibition of sporulation was primarily a secondary effect not related to its incorporation into DNA. For example, effects on the cytoplasmic membrane might be expected to interfere more with sporulation than with growth²⁰. BUdR had no effect on the sporulation capacity of wild-type *B. subtilis*, however, which suggests that a simple phenotypic effect of this sort is unlikely. At present it must be assumed that the inhibitory effect of BUdR is a consequence, for the most part, of its incorporation into DNA during chromosome replication at the onset of sporulation. This incorporation might interfere with the regulation of the process in some way, perhaps by causing an alteration in transcription due to tighter binding of regulatory proteins or by an alteration in the stability of chromosome-membrane complexes as has been suggested for other systems^{1,2,20}.

I thank W. F. Park for technical assistance and A. Ellis for electron microscope examinations.

Transcription of a mammalian sequence under phage λ control

RECOMBINANT DNA techniques have recently enabled bacterial plasmids carrying eukaryotic sequences synthesised *in vitro* from purified mRNAs to be constructed and cloned in *Escherichia coli*^{1–10}. We show here that a rabbit globin sequence is not transcribed in *E. coli* when carried by the pCR1 plasmid. However, after transfer into phage λ , the globin sequence is transcribed under λ control. Thus, there is no basic hindrance to the transcription of a specific mammalian sequence in *E. coli*.

Recombinant plasmids containing globin cDNA obtained as previously reported by us¹, carried only

a relatively short part of the globin sequence. For the construction of another series of plasmids¹, much longer double-stranded globin DNA molecules were synthesised from cDNA copies of purified globin mRNA with reverse transcriptase in a 'self-priming' reaction⁸. A similar procedure for the synthesis of double-stranded DNA from cDNA has been independently devised by others^{6–9}. Plasmids were thus obtained with the α or the β globin gene from rabbit⁷ and mouse¹⁰.

The protocol used for these experiments^{1,7,10} involved the reconstruction of an *EcoRI* site on each side of the integrated sequence. Analysis of many hybrid plasmids revealed that these two *EcoRI* sites were present only rarely, but were present, however, on one of the rabbit plasmids, pCR1 β G19, which carries the entire β globin sequence. Since there is also an *EcoRI* site within this sequence, digestion of pCR1 β G19 DNA yields, in addition to the parent plasmid DNA, two smaller fragments, A and B, 410 and 210 base pairs long respectively, which correspond to the 5' (A) and 3' (B) ends of globin mRNA¹.

To determine whether the globin sequence is transcribed in *E. coli* harbouring pCR1 β G19, unlabelled RNA was extracted from exponentially growing cells, hybridised with ³H-globin cDNA, and the hybrids monitored with nuclease S1. There was little or no detectable globin RNA in conditions which we estimate would allow the detection of less than one molecule of globin RNA per bacterial cell (Table 3, line 1). We then explored the possibility that the rabbit sequence could be transcribed in *E. coli* when carried by another vehicle such as phage λ .

pCR1 β G19 DNA was digested to completion with *EcoRI*, and the fragments were recombined with the DNA of

pCR1 β G19 DNA was purified and digested by *EcoRI* as described¹. It was next recombined, in a 3:1 molar ratio with *EcoRI* digested DNA of phage 589, in the presence of T4 DNA ligase at 4 °C (refs 11, 18). The calcium method (slightly modified, as described in refs 11 and 18) was used for transfection in C600_r⁺ m_k⁺. Infective centres were plated in the presence of W3110 *polA*[−] in a 1:1 ratio with C600_r⁺ m_k⁺. On the mixed lawn, *red*[−] phages form small turbid plaques at 37 °C, which are easily scored by stabbing on to C600 and W3110 *polA*[−] (ref. 11). 14 *red*[−] phages (the putative recombinants) were re-isolated twice; stocks were made, and lysogens were isolated from a lawn of C600 spotted at 32 °C with about 10⁸ phages. After purification, the lysogens were grown at 32 °C in broth. The DNA of the 14 independent lysogens was then extracted from 5 ml of culture, immobilised on nitrocellulose filters and hybridised with 1,000 c.p.m. of ³H-globin cDNA (7 × 10⁶ c.p.m. μ g^{−1}, prepared as in ref. 8), for 18 h at 37 °C in 2 × SSC–50% formamide pH 7.2; the reaction volume was 4 μ l (refs 1, 14, 15). Note that the ³H-cDNA, made from a mixture of α and β globin RNAs, consists of about 2/3 of β chain DNA. The table also shows the ratio (long—short)/short of c.p.m. hybridised with long or short cDNA fractionated in a sucrose gradient as described in the text.

Four lysogens were grown in 63 medium supplemented with glucose, casaminoacids and vitamin B1 (ref. 16), for pulse labelling of 10 ml of culture with ³H-uridine (CEA, 25 Ci mM⁻¹, 20 μ Ci ml⁻¹). The RNAs were extracted as before¹⁶ and hybridised at 37 °C for 4 h, in a final volume of 4 μ l of 2 $\times$ SSC–50% formamide, to filters carrying 1 μ g of λ , pCR1 β G19 or pCR1 DNA, or no DNA. Filters were processed as usual¹⁵. There is no cross hybridisation between the phage, plasmid and globin sequences as shown in the first line of the table, where λ RNA from a overproducing strain¹⁸ was labelled and hybridised in similar conditions.

phage 589 in our collection. This phage was derived from λ plac5 by a series of *in vivo* and *in vitro* manipulations (P.K. and D.G., in preparation). It has lost the *EcoRI* *lac* fragment (a 14% deletion) and has only one *EcoRI* sensitive site located within the *red* gene of λ (ref. 12). Integration of foreign DNA at this site makes the phage *red*⁻ so that recombinants are easily scored as small plaque formers on a mixed lawn (1:1 of *polA*⁺ and *polA*⁻ bacteria (ref. 12 and P.K. and D.G. in preparation). Recombinants of phage 589 (which carries the *cl*857 mutation) lysogenise easily at 32 °C, at least at high multiplicity, in spite of the partial cold-sensitive character of such phages (F. Bregegere, J. Leal and P.K., in preparation). Since pCR1 DNA is too large to be accommodated within phage 589, the only recombinants which could be obtained are those carrying the A or B globin fragment, or both.

Recombinants were isolated, and a lysogen made with ³H-globin cDNA (ref. 1). Of 14 strains examined, 13 carried the lysogens, denatured, and immobilised on nitrocellulose

filters for hybridisation in formamide¹³ under paraffin oil¹⁴ with ³H-globin cDNA¹. Of 14 strains examined, 13 carried a globin sequence. Hybridisation was further carried out with cDNA fractionated in a sucrose gradient into short cDNA (< 250 nucleotides) or long cDNA (> 250 nucleotides) and with ³H-pCR1 β G1 DNA. This allowed the identification of phages carrying the A or the B fragment, or both. In five strains out of thirteen, hybridisation with short cDNA was significantly reduced. These strains, therefore, are of the λ -A type, while the others are λ -B, or λ -A-B. Monitoring with ³H-pCR1 β G1 DNA, a plasmid which carries only a short part of the globin sequence¹, indicated preferential hybridisation with DNA from the λ -A strains. This suggests that the portion of the globin sequence in pCR1 β G1 is mostly in the A region, and that (with two possible exceptions) the eight other strains are λ -B rather than λ -A-B.

Is the globin sequence transcribed in non-induced or induced lysogens, and if so, is it transcribed from the correct or the anti-sense strand?

Attention was first focused on four λ -A strains. We took advantage of the availability of the globin sequence in two unrelated molecular vehicles (pCR1 and λ) (which allow it to be produced in large amounts) to assay transcription from λ -A by hybridisation to a large excess of pCR1 β G19 DNA. Four λ -A lysogens were pulse labelled with ³H-uridine at 32 °C (3 min) or at 42 °C (2 min after an incubation of 3 min at 42 °C; early transcription in the *red* region is known to be maximal at about this time¹⁵). The radioactive RNAs were extracted and hybridised to excess pCR1 β G19 and pCR1 DNA on filters. In all cases transcription of the globin sequence occurred in the induced, but not in the non-induced lysogens (Table 2). The rough assumption can be made that about 70% of the radioactivity hybridised to λ DNA reflects the *l* strand transcription of about 16% of the λ chromosome, that is, 7,000 base pairs. The transcription of 410 base pairs of globin sequence should correspond to about 3.5% that of λ , in relatively good agreement with figures of 2 to 5% derived from data in Table 2.

To determine whether the coding strand is transcribed in at least some of the strains, unlabelled RNA was extracted from non-induced lysogens and lysogens induced for 7 min. The unlabelled RNAs were hybridised with ³H-cDNA. On treatment with nuclease S1, protection of the ³H-cDNA is observed in two strains out of four, demonstrating that, in these two strains, the coding strand is transcribed (Table 2). When similar experiments were carried out with the other strains, transcription of the coding strand was observed in a total of eight strains out of the thirteen examined.

On methodological grounds, the above results illustrate the use of two unrelated vectors (λ and pCR1) carrying a

Table 3 Transcription of the globin sequence assayed by hybridisation to ³H- β globin cDNA.

200 ml of C600 *r*_k⁻ *m*_k⁻ *recBC*⁻ (pCR1 β G19) were grown (in broth at 37 °C) as well as 200 ml of the various lysogens (grown in broth at 32 °C and induced at 42 °C for 7 min) and in some cases, 200 ml of the non-induced lysogens. Cells were collected at a density of 4 $\times$ 10⁸ bacteria per ml. The RNAs were extracted as before^{16,18} and concentrated to about 1 mg ml⁻¹. 100 μ l were hybridised for 16 h at 70 °C with 700 c.p.m. of ³H-globin cDNA copied from the β chain (7 $\times$ 10⁶ c.p.m. μ g⁻¹ as before) in a final volume of 120 μ l in 2 $\times$ SSC. After incubation, the samples were divided into two, and precipitated with TCA after previous or no treatment with nuclease S1. A background of 30 c.p.m. was subtracted before calculating the percentage resistance.

I, induced; NI, non-induced.

similar DNA piece as a general tool for transcriptional studies (DNA from one recombinant can serve to monitor transcription from the other). Our results also show that *Eco*RI sites constructed *in vitro* have the expected properties for both endonuclease attack⁷ and *in vitro* recombination. In this process, the four more likely combinations (integration of fragment A, or B, in either direction) were observed suggesting that recombination occurred at random.

We show that a specific mammalian sequence can be transcribed from the coding strand in *E. coli* K12 under phage λ control. This is not unexpected in view of the known properties of the phage transcriptional systems¹⁶. The anti-termination properties of the *N* gene product make it likely that a number of sequences, including eukaryotic ones, can be transcribed under λ control, once integrated in appropriate phage early regions. This work provides an example of this, as a necessary step on the road to eukaryotic gene expression in *E. coli*.

Biohazards associated with the experiments described in this publication have been examined previously by the French National Control Committee. The experiments were carried out accordingly in P2-like conditions (in the NIH nomenclature). This work was supported by grants from CNRS, INSERM and DGRST in Paris, and by the FNRS in Geneva. One of us (F.R.) was supported by a short-term EMBO fellowship.

We thank Professor F. Gros for his interest and support, Dr M. Jacquet for the gift of S1 nuclease and advice, and Mrs A. Bernardin for typing the manuscript.

Molecular characterisation of the tyrosine tRNA genes of yeast

MANY of the tRNA genes of yeast are observable genetically as nonsense suppressors¹. In particular, the set of unlinked suppressor loci *SUP2* to *SUP8* and *SUP11* have been shown to insert tyrosine at nonsense codons in yeast iso-1-cytochrome c^{2,3}. Direct biochemical evidence for the presence of suppressor tRNA in yeast strains bearing these suppressor genes has been obtained using *in vitro* translation systems^{4,5} and by the demonstration that a new minor tyrosine tRNA species with a suppressor anti-codon appears in a *SUP5* strain⁶. Although these

findings suggest that there are eight different loci in yeast which code for tRNA^{tyr}, only a single nucleotide sequence has been observed for tyrosine tRNA in wild-type yeast strains⁷. Thus it seems that all eight genes may share a common base sequence, at least in their structural regions. Because the yeast tRNA^{tyr} *SUP* genes occupy known positions on the genetic map⁸ and are complementary to a well characterised RNA molecule they are attractive candidates for molecular analysis. As a first step, we have labelled yeast tRNA^{tyr} with ¹²⁵I and have hybridised this probe to electrophoretically fractionated *Eco*RI fragments of yeast DNA; eight *Eco*RI fragments of different sizes hybridise to tRNA^{tyr}.

Figure 1 shows the molecular weight distribution of *Eco*RI-cleaved yeast DNA and documents the efficiency with which the DNA can be transferred from the gel to a nitrocellulose filter. In addition to the three prominent bands of molecular weight (mw) between 1 and 2 × 10⁶, which contain ribosomal cistrons, there is a continuous distribution of DNA sizes up to > 10⁷ mw (ref. 9). Comparison of the two curves in Fig. 1b shows that *Eco*RI fragments between 5 × 10⁵ and 5 × 10⁶ mw are transferred to nitrocellulose¹⁰ with 80% efficiency and that the transfer efficiency decreases significantly for DNA fragments larger than 5 × 10⁶ mw. The structure of the DNA banding pattern is retained remarkably well through the transfer process, as may be seen by comparing the gel stain pattern and filter autoradiogram (Fig. 1a).

DNA from yeast strain B596 (ref. 11) was *Eco*RI-restricted, electrophoresed on a 0.7% Agarose gel, and then transferred, as denatured DNA, to nitrocellulose filter strips¹⁰. After drying, the filter strips were hybridised to ¹²⁵I-labelled tRNA^{tyr}. The tRNA^{tyr} used for hybridisation was partially purified from total yeast tRNA by the acylation-BD cellulose procedure of Gillam *et al.*¹². The derivatised, ³H-tyrosine-aminoacylated tRNA^{tyr}

Fig. 1 Agarose gel fractionation of *Eco*RI-cleaved total yeast DNA. *a*, High molecular weight ¹⁴C-labelled yeast DNA was prepared by lysing glucanase-treated cells in sarkosyl and purifying the released DNA by velocity sedimentation through sucrose and isopycnic banding in CsCl. A limit *Eco*RI digest of this yeast was electrophoresed on a 0.7% Agarose slab gel, stained with ethidium bromide, and then transferred to nitrocellulose by the procedure of Southern^{10,11}. The top strip shows the banding pattern of *Eco*RI-cleaved DNA from bacteriophage λ , electrophoresed on the same gel. The middle strip shows an autoradiogram of the nitrocellulose strip containing the yeast *Eco*RI fragments. The bottom strip is a photograph of the yeast ethidium bromide staining pattern. *b*, On a parallel well of the same gel described in (*a*) an identical aliquot of *Eco*RI-cleaved yeast DNA was electrophoresed. The gel was sliced and the individual slices counted (broken line). The nitrocellulose strip whose autoradiogram is shown in (*a*) was also sliced and counted (solid line). The counting efficiency was the same for the gel and nitrocellulose filter slices so the two curves in (*b*) are a direct measure of the efficiency with which the DNA was transferred to the filter.

was eluted from BD cellulose in 1M NaCl, 11% ethanol. It was then iodinated with ^{125}I in the presence of peroxidase and H_2O_2 . In our hands this procedure gave material with a specific activity two orders of magnitude higher than we could achieve by *in vivo* labelling with ^{32}P . An autoradiogram of a hybridised filter strip is shown in Fig. 2a; eight discrete hybridisation bands are present.

To test conclusively whether tRNA^{tyr} molecules were responsible for the eight hybridisation bands observed in Fig. 2a, competition hybridisation was performed using cold competitor tRNA^{tyr} that had been highly purified by a procedure differing from that used to prepare tRNA^{tyr} for iodination. Specifically, the competitor was purified by sequential chromatography on BD cellulose, first as uncharged tRNA^{tyr} then as aminoacylated $\text{tyr-tRNA}^{\text{tyr}}$ (ref. 13); finally, the material was further purified by chromatography on Sepharose¹⁴ using a reverse ammonium sulphate gradient. Competition of the ^{125}I -tRNA hybridised to all eight bands is observable at an unlabelled tRNA^{tyr} concentration of $0.1 \mu\text{g ml}^{-1}$; competition is virtually complete at $1.0 \mu\text{g ml}^{-1}$. The estimated concentration of ^{125}I -labelled tRNA^{tyr} in the hybridisations was $0.1 \mu\text{g ml}^{-1}$. In subsequent experiments the same eight band pattern shown in Fig. 2a was obtained by hybridisation of yeast tRNA^{tyr} which had been purified to apparent homogeneity before labelling with ^{125}I . These data strongly suggest that each of the eight observed bands arises from hybridisation to a tRNA^{tyr} gene.

The molecular weights of the eight *Eco* RI fragments that hybridise to ^{125}I -labelled tRNA^{tyr} were estimated from their electrophoretic mobilities. Band positions on autoradiograms

Fig. 2 Hybridisation of ^{125}I -labelled tRNA^{tyr} to yeast *Eco* RI fragments. Iodinated tRNA^{tyr} with a specific activity of $>5 \times 10^7$ c.p.m. μg^{-1} was hybridised to DNA immobilised on nitrocellulose strips in 60% formamide, 1.15 M sodium acetate, pH 6 at 40°C for 3 h. The hybridisation conditions were similar to those used by Birnstiel¹⁶ for tRNA hybridisations. After extensive rinsing and RNase treatment, autoradiograms of the filter strips were recorded. Hybridisation was carried out in the presence of a, 0; b, $0.1 \mu\text{g ml}^{-1}$; and c, $1 \mu\text{g ml}^{-1}$ of purified, unlabelled tRNA^{tyr} .

Fig. 3 Agarose gel mobilities of the yeast *Eco* RI fragments that hybridise to tRNA^{tyr} . The arrows show the positions of the eight hybridising fragments, A-H. λ *Eco* RI fragments, $\circ$; yeast rDNA fragments I and III, Δ . Molecular weights of the λ fragments are from ref. 15; values for the yeast rDNA fragments are calculated from data in ref. 16.

of the nitrocellulose filters were standardised with ^{14}C -labelled *Eco* RI fragments of bacteriophage λ (ref. 15) and also with yeast rDNA fragments I and III, which were located by hybridisation with ^{32}P -labelled 18 and 28S rRNA¹⁶. A plot from a typical gel is shown in Fig. 3. Approximate molecular weights for the hybridising fragments ($\times 10^3$) are as follows: A ≈ 9 ; B, 5.8; C, 4.5; D, 4.2; E, 3.5; F ≈ 0.6 ; G ≈ 0.6 ; H ≈ 0.4 .

Because the base sequence of yeast tRNA^{tyr} does not contain an *Eco* RI site, each DNA sequence that hybridises to this tRNA should lie within a single *Eco* RI fragment. Consequently, the number of hybridisation bands observed should equal the number of tRNA^{tyr} genes, which seems to be eight. The length of the *Eco* RI fragment which contains each of these eight genes will be determined by the nature of the chromosomal DNA sequences which lie to either side of the tRNA^{tyr} gene. Our results indicate that this neighbouring DNA has different characteristics for different tRNA genes, since the length of accompanying DNA varies from less than 1,000 to more than 12,000 base pairs for different restriction fragments which hybridise ^{125}I -tRNA^{tyr}.

An indication that one of the eight loci differs from the others within the tRNA gene is given by our hybridisation results (Fig. 2a and b). Band D contains noticeably less hybridised tyrosine tRNA than the more intense bands C and E on either side. We have observed band D to be consistently less intense than its immediate neighbours in a large number of experiments using DNA from several different haploid and diploid yeast strains. The data in Fig. 1b indicate that systematic loss of band intensity at low and high molecular weights is expected due to incomplete transfer of DNA to the nitrocellulose. This effect fails to explain the diminished intensity of band D, however, which is in a region of high, constant efficiency and is closely bracketed by more intense bands. Although differences in the number of tRNA^{tyr} genes at each locus remain a possible source of variable band intensity, the existing genetic data favour the hypothesis that each locus contains a

single copy¹⁷. To identify which suppressor gene corresponds to each of these bands, the procedures described here can be applied to DNA from yeast strains either deleted for particular suppressor loci or aneuploid for one of the relevant chromosomes. Further progress in the structural analysis of individual tRNA¹⁷ genes and the adjoining DNA sequences will depend on the successful molecular cloning of the *Eco* RI fragments that we have identified. The ¹²⁵I-tRNA probe described here should be well-suited to screening plaques or colonies for the presence of tDNA¹⁷ sequences in recombinant genomes.

We thank Gordon Tener for advice and for providing yeast tRNA and Gayle Lamppa for technical assistance. This work was supported by the US NIH and Washington State Heart Association.

Nucleotide sequence of the yeast 5S ribosomal RNA gene and adjacent putative control regions

In bacteria, the sequence of several promoters has been determined and some of the features of their interaction with RNA polymerase, repressors and other regulatory molecules are beginning to be determined^{1,2}. In eukaryotes, however, the isolation and analysis of the DNA structures involved in the regulation of transcription has not yet been achieved. Recent advances in techniques for cloning eukaryotic DNA in bacterial plasmids³ have allowed the isolation of genetic segments whose structure and function can be studied in detail. Using these methods we have isolated a DNA fragment containing the 5S ribosomal RNA gene. The 5S RNA seems to be a primary transcript in yeast^{4–6}; therefore the flanking regions of the 5S gene should contain the putative promoter and termination regions. We report here the nucleotide sequence of *Saccharomyces cerevisiae* 5S DNA and these flanking regions.

Yeast DNA and the plasmid vector pSF2124 (ref. 7) were digested with *Eco*RI, ligated, and used to transform a derivative of *E. coli* K12, DG-75 (a F[–] derivative of DG73 ref. 8)). Recombinant clones were selected by ampicillin resistance and inability to produce colicin E1. Recombinants containing 5S rDNA were selected by hybridisation with purified yeast 5S rRNA. A clone (pDB25) containing

a 2,520 base pair yeast DNA fragment which hybridises with 5S rRNA was obtained.

The tentative position of the 5S rRNA gene within the 2,520 base pair fragment was determined by restriction mapping with endonucleases *Hae*III, *Alu*I and *Hpa*II and by hybridisation of the restriction fragments with ¹²⁵I-labelled yeast 5S rRNA (P.V. *et al.* in preparation). The sequence of 5S RNA of *S. cerevisiae*⁸ and of the related species, *S. carlsbergensis*⁹, predicts a *Hae*III site eight base pairs from the 3' end of the gene. Therefore as indicated in Fig. 1, we isolated the two *Hae*III fragments (1,120 and 520 base pairs, respectively) which encompass the 5S rRNA gene, labelled them at their 5' ends with γ -³²P-ATP and polynucleotide kinase, and digested them with *Hpa*II. Two fragments, each containing a complementary portion of the 5S RNA gene, of 300 (a) and 400 (b) base pairs were isolated by preparative gel electrophoresis and partially sequenced from their ³²P-labelled *Hae*III ends. DNA was sequenced by using the chemical cleavage technique developed by Maxam and Gilbert⁹. Figure 2 shows an autoradiogram of the electrophoretic separation of oligonucleotides resulting from base specific cleavages of fragments a and b. The sequence can be directly read from the autoradiogram as exemplified in the figure for the first 10 nucleotides. The experiment with fragment a (Fig. 2a) generated a sequence comprising 112 bases from the 5S rRNA gene and 61 bases from the region adjacent to the 5' end (termination region). An *Alu*I fragment of 160 base pairs containing this region was also sequenced (P.V. unpublished). The sequence of fragment b (Fig. 2b) furnished a sequence of 68 base pairs, 8 from the 5S gene and 60 from the region adjacent to its 3' end (initiation region). The complete sequence of the 5S RNA gene and adjacent regions is shown in Fig. 3. The sequence of other regions, comprising about 70%, of the 2,520 base pair fragment has been completed and will be reported elsewhere.

The sequence of most of the 5S RNA from *S. cerevisiae* has been reported by Miyazaki¹. However, a small region around the 35th position (from the 5' end) remained uncertain¹. The sequence we have determined for the 5S RNA

promoter region for *Xenopus* oocyte 5S RNA genes. There is no obvious relationship between the structures of this region and the region we have sequenced. The fundamental structural relationships which determine transcription promotion in eukaryotes are as yet difficult to perceive.

In contrast, at the end of the 5S gene there is a striking stretch of As in the coding strand (Fig. 3). We believe this to be a termination signal for RNA polymerase. Termination in other systems may be related to A-rich regions. For example, variable runs of Us have been found at the 3' end of 4S (ref. 11) and 6S (ref. 12) RNAs of λ phage, a small RNA from phage ϕ 80 (ref. 13) and the attenuator region of tryptophan mRNA of *E. coli*¹⁴. There is no evidence for transcription of this A region in yeast; however, transcription and rapid processing has not been eliminated. In eukaryotes, Brown and Brown¹⁵ have found a much shorter AT-rich region at the 5' end of the *Xenopus* 5S RNA gene and postulated the sequence TTTT AAAA as part of a transcription termination signal.

RNA polymerase binding and *in vitro* transcription experiments will be necessary to determine the role of these sequences in selective gene transcription.

This research was supported by a grant from the National Institutes of Health. We thank J. Shine for advice and A. Maxam and W. Gilbert for providing a detailed protocol of their DNA sequencing method before publication.

Promotor region for yeast 5S ribosomal RNA

We have sequenced the DNA region immediately preceding the structural gene for the 5S ribosomal RNA of yeast (*Saccharomyces cerevisiae*). Since the 5S RNA, a component of the larger ribosomal subunit, has a 5' triphosphate^{1,2}, this molecule is likely to be the direct product of the gene, unmodified by maturation at the 5' end. Thus the DNA sequence immediately before this region must contain the recognition sequences where the RNA polymerase binds to begin synthesis, that is, this sequence must represent a eukaryotic promoter.

T. D. Petes, P. Wensink and D. Botstein (unpublished) isolated a series of plasmids containing sheared DNA from a diploid yeast strain (A364a+D4, provided by L. H. Hartwell). Digestion of those containing yeast rDNA with *EcoRI* generated a map of the ribosomal area (T. D. Petes, L. Hereford and K.G.S., in preparation), shown in Fig. 1. The map was derived by noting the associations

between RI fragments in different clones carrying some but not all of the ribosomal repeat unit, and hybridisation of mature 5S, 5.8S, 18S and 28S rRNAs to the individual *EcoRI* fragments. Only fragment B, the second largest *EcoRI* fragment, 2,600 base-pairs long, hybridised to the 5S RNA. Sequential cleavage with *SmaI* (from *Serratia marcescens*) and *EcoRI* then oriented RI fragment B with respect to its neighbours.

The nucleotide sequence of yeast 5S rRNA¹ suggested several restriction endonuclease sites in the structural gene, the one of primary interest being a *HaeIII* (from *Haemophilus aegyptius*) cut eight nucleotides from the 5' end of the RNA. To construct a restriction map of the *EcoRI* B fragment, we end-labelled it with polynucleotide kinase and λ -³²P-ATP, cut the fragment close to either one or the other end with *SmaI* or *HindIII* (from *Haemophilus influenzae*) (Fig. 1), and then examined partial digests of the resulting long, uniquely terminally labelled fragments with a series of restriction enzymes³. Sites for two which cleaved fragment B, *HaeIII* and *TaqI* (from *Thermus aquaticus*), are shown in Fig. 1.

We then sequenced⁴ the ends of all of the *HaeIII* fragments in order to identify which fragment junction lay within the 5S rRNA gene. From this *HaeIII* junction, we then sequenced out 100 bases before the gene, and on the other side, the gene itself (Fig. 1). Sequences at the extremities of this region were confirmed by sequencing towards the gene on the complementary strands from each of the two outlying *TaqI* cleavage sites. Figure 2 is an autoradiograph from one of these strands: a striking poly(dA) run that terminates the gene. Figure 3 shows the DNA sequence derived⁴ from analogous patterns on the four strands, and the corresponding 5S rRNA.

Our structure for 5S rDNA confirms most of the RNA sequences worked out by Miyazaki¹ for *S. cerevisiae* and by Hindley and Page⁵ for *S. carlsbergensis*, and generally agrees with one from *Torulopsis utilis*⁶. Except for two base changes (at positions 61 and 73) in *T. utilis*, the differences between the sequences are most likely to be minor errors in RNA sequencing: failures in ordering a series of pyrimidines within a single T₁ fragment (an extensive comparison of these sequences is in ref. 6).

The restriction maps and nucleotide sequences determine the direction of transcription of the 5S gene to be from right to left on the *EcoRI* B fragment, as shown, and thus

Fig. 1 Restriction endonuclease cleavage map of cloned *S. cerevisiae* rDNA. The order of fragments (A-G) released from the ribosomal repeat unit by *EcoRI* is shown at the top, and at the bottom, sites in fragment B for four other endonucleases. Arrows represent precursor RNAs, and thickened lines in the lower map indicate end-labelled DNA strands which were sequenced. (*EcoRI* map courtesy of T. D. Petes, L. Hereford, and K. G. Skryabin, in preparation).

Fig. 2 Sequence pattern from one DNA strand in the region immediately following the structural gene for 5S rRNA. Partial, base-specific cleavage products extending from a labelled *TaqI* restriction endonuclease site towards the 5S gene (Fig. 1) are displayed. The specificity of the four DNA cleavage reactions employed was, from left to right, A > G, G, C, and C + T. Between the two guanines are 29 adenines, with every second one indicated on the autoradiograph. The centre of this poly(dA) region lies 142 bases from the startpoint of 5S RNA transcription, shown in Fig. 3. Valenzuela *et al.*¹⁰ (accompanying paper) find 21 adenines in this region in DNA cloned from another *S. cerevisiae* strain. To obtain the pattern displayed, *EcoRI* fragment B, isolated from the plasmid pY1R-B-3, was cleaved with *TaqI* and the products dephosphorylated with alkaline phosphatase, rephosphorylated with ³²P, and isolated on an 8% polyacrylamide slab gel¹. The *TaqI* fragment encompassing the 5S rRNA gene (Fig. 1) was then cleaved with *HaeIII*, and the end-labelled fragments separated on a second polyacrylamide gel and sequenced by partial, base-specific chemical degradation, gel electrophoresis, and autoradiography¹. The centre of the oligo-(dA) pattern in the autoradiograph is 68 bases from the labelled end of the fragment.

to be opposite in direction to the major 18S and 28S rRNA synthesis.

The region immediately to the left of the initial triphosphate in Fig. 3 must be the site for a yeast RNA polymerase. The 5S rDNA of animal cells is transcribed by RNA polymerase III (ref. 7); thus it is likely that this sequence contains the promoter for yeast polymerase III. Several elements in this yeast promoter sequence are curious (Fig. 4). There is a purine/pyrimidine bias in the 90 base pairs before the triphosphate, with 60 of 90 purines on the lower strand. There is no particular A-T/G-C bias. There is a triple partial repeat of an 18-base-pair-long sequence; 14 bases are repeated in the promoter and 11 bases early in the gene. This may be a remnant of the process that created this DNA region.

The promoter and the gene are flanked on the left and right with poly(dA-dT) rich regions almost serving to identify the gene itself (Fig. 3). Before the promoter there is a region of 16 A-T pairs; after the gene there is an oligo(dT) stretch 29 bases long. The sequence of Ts at the end of the gene is reminiscent of a number of bacterial termination sites (reviewed in ref. 8), but the poly (U) sequence, found on bacterial RNAs, would have to be removed.

If this yeast promoter is compared with the bacterial promoters known, no homologies are seen, nor might they be expected. In bacteria, the RNA polymerase interacts with a region of the DNA comprising some 40 bases before the beginning of RNA (reviewed in ref. 8). The polymerase protein also shields the first 18–20 bases that will be transcribed against attack with pancreatic DNase. The bacterial promoter's best defined region is the 'Pribnow box', a 7-base-pair-long approximate homology to the sequence TATPuATG centred on one turn of the DNA helix (8–11 bases) before the initiation point of the RNA chain. Another region defined by prokaryotic work is centred about 35 bases before the beginning of the messenger. Here there are some homologies, involving a GTTG sequence, and mutations in both the *lac* and the lambda promoters show that this region is important⁷. Furthermore, in bacteria the area around 60 nucleotides before the beginning of the messenger can be a site for positive control proteins. The CAP factor (the cyclic AMP binding protein that stimulates promoters such as *lac*, *gal* or *ara*) and the lambda repressor (in its *alter ego* of a positive control factor for its own synthesis⁹) bind there, often to palindromic sites.

The yeast sequence does not resemble any of the common

Fig. 3 Nucleotide sequences before, within, and beyond the *S. cerevisiae* gene for 5S rRNA.

Kinetics of rhodopsin at room temperature measured by picosecond spectroscopy

The photoinduced intermediates of the visual photoreceptor rhodopsin have been studied by optical spectroscopy in low temperature glasses and at room temperature. The primary changes in the absorption spectrum of rhodopsin were first observed at 77 K by Yoshizawa and Kito¹ then by Grellman *et al.*² and Yoshizawa and Wald³. The first intermediate observed, prelumirhodopsin (bathorhodopsin) exhibits a maximum at 545 nm and has been assigned to the primary isomerisation step of the rhodopsin polyene chromophore. The room temperature kinetics of formation and decay of an intermediate species absorbing at 560 nm were measured by Busch *et al.*⁴ using picosecond spectroscopy. This original work revealed that this species, assigned as prelumirhodopsin, was formed within 6×10^{-12} s and decayed with a lifetime of 3×10^{-8} s. Several technical innovations in picosecond spectroscopy⁵⁻⁷ now enable us to monitor spectra changes between 400 nm and 1,500 nm as a function of time with ± 0.02 absorbance unit resolution. We report here a complete difference spectrum for prelumirhodopsin

at room temperature mapped on a picosecond time scale. These studies show that the loss of rhodopsin and the rise of prelumirhodopsin are kinetically consistent. If care is taken to avoid photon saturation no 'ghost' species appear in the region of 400-440 nm as has been reported previously^{8,9}.

Bovine rhodopsin samples, solubilised in Ammonyx LO detergent, were prepared as described in ref. 10. The optically clear samples contained between 1 and 2×10^{-4} M rhodopsin (that is, 4-7 absorbance units per cm at 500 nm) and the absorbance ratios for 400 nm/500 nm were 0.20 ± 0.02 . For the experiments described, special care was taken to shield the sample from all spurious light emitted by the flashlamp or amplifier system, and all the experiments were conducted in the dark or under dim red light. Measurements were made in a 2-mm optical path length cell. We estimate that less than 15% of the sample in the optical path was bleached per excitation pulse. For each kinetic observation at a given wavelength, the sample was mixed between successive shots and completely replaced after five shots.

The experimental apparatus is described in detail in ref. 5. A single pulse is selected from the train of pulses generated by a Nd³⁺ glass laser emitting at 1,060 nm. The pulse is amplified and the frequency doubled to 530 nm. Thereafter it is split into two parts; one acting as the excitation pulse and the other inducing the interrogation continuum in a benzene or alcohol cell. This continuum is segmented into several spatially equidistant pulses by an echelon thereby providing the means for observing time resolved absorption spectra. These continuum pulses, which are too weak in intensity to cause any measurable excitation, are detected by a SIT vidicon and subsequently analysed, averaged, and displayed by a Nova computer. Care is taken to avoid dispersion and saturation effects by following the practice of timing the excitation pulse with

Fig. 1 Absorbance changes plotted against pulse energy. A straight line with an intercept at zero would indicate that no saturation occurred within this region of excitation pulse energy where our experiments were performed.

each wavelength and of making certain that the vidicon was used in its linear range.

Particular care was taken to eliminate photon saturation of the sample since rhodopsin, as most other highly sensitive biological molecules, can easily be saturated by an intense light pulse which may produce erroneous multiphoton events. Changes in ΔA were examined as a function of the laser pulse intensity as shown in Fig. 1 and data were used only when they fell within the linear range of this plot. An additional indication that the system is not saturating is shown in Fig. 2 in which the photoinduced ΔA increases proportionally with increasing sample concentration at constant excitation intensity.

Excitation of rhodopsin by a single, 6-ps 530-nm pulse resulted in the bleaching of the rhodopsin band and simultaneous formation of prelumirhodopsin. The entire difference spectrum, recorded 60 ps after excitation is plotted in Fig. 2. This spectrum is characterised by:

- (1) The bleached rhodopsin band at 430–510 nm with a maximum ΔA at 485 nm.
- (2) Formation of a band at 530–680 nm with a maximum ΔA at 580 nm.
- (3) An approximate isosbestic point at 525 nm.

This difference spectrum is in approximate agreement with the previously reported data for low temperature glasses in digitonin², rhodopsin in Ammonyx LO (ref. 10), and rhodopsin in intact retina¹¹. The kinetics indicate that the 485-nm band bleaches and the 580-band maximum arises within 6 ps as shown in Fig. 3.

There is one striking difference between the room temperature picosecond spectrum and those observed in low temperature glasses. The ratio of maximum and minimum ΔA in the difference spectrum observed at room temperature is 1:1. At low temperatures under a photo-stationary equilibrium, which is carefully established to exclude formation of isorhodopsin, this ratio is 2.5:1 or 3:1 (refs 10, 11). In addition the isosbestic point is located at 525 nm at room temperature versus 515 nm in low temperature glasses.

The source of this discrepancy is not clear. It is possible that temperature affects the band width and shape to some extent, however, it is more probable that at room temperature the excited rhodopsin decays not only to a prelumirhodopsin state but back to rhodopsin or other states via channels which are not open at low temperatures due to the rigidity of the species. To elucidate the operative mechanisms, we are investigating transient formation at various temperatures and attempting to determine quantum yields of formation of prelumirhodopsin as a function of temperature. It is interesting to note that a relative increase of the prelumirhodopsin band intensity at low temperatures would result in the shift of the isosbestic point to 515 nm,

Fig. 2 Difference spectrum observed 60 ps after excitation. The positive ΔA band is assigned to prelumirhodopsin while the $-\Delta A$ is due to the bleached rhodopsin. The reproducibility of each point is $\pm 0.02 \Delta A$ units. $\blacktriangle$, A 1.4/2 mm; $\bullet$, A 0.8/2 mm.

Fig. 3 *a*, Formation of the prelumirhodopsin band with a maximum at 580 nm induced by a 530-nm 6-ps pulse. $\blacktriangle$, 580 nm; $\bullet$, 480 nm. *b*, Depletion rate of the rhodopsin band at 480 nm after excitation with the same picosecond pulse. Similar kinetics are observed over the entire spectrum. Both figures represent an average of five kinetic records. The variance is given by the error bars.

which is observed at 77 K. This tends to support the above proposition that the 1:1 ratio observed at room temperature is probably due to active additional decay channels which deplete the excited state.

Rosenfeld and co-workers⁹ have reported the formation of isorhodopsin between 380 nm and 475 nm at 50 ns. Bensasson *et al.*⁸ reported a similar absorption occurring at 50 ns which was attributed to a new absorption due to prelumirhodopsin. As noted above, we have not observed formation of any new species between 410 nm and 430 nm between 6 ps and 100 ps nor do we have evidence for the early formation of hypsorhodopsin, the species observed by Yoshizawa¹² at liquid helium temperatures.

In view of the general agreement of our spectrum (Fig. 2) with regard to the shape, width, maxima, and kinetics (Fig. 3) with the previously published spectra for prelumirhodopsin at low temperatures, we assign the species we observe at room temperature to prelumirhodopsin. We conclude that within our time resolution of 6 ps, the only species formed at room temperature during the first 100 ps is prelumirhodopsin.

We thank Professor Yoshizawa for discussions and the US Japan Scientist Exchange Program for vision research for the support provided to him. M.L.A. received a grant from the US National Eye Institute.

matters arising

Transition probability and cell-cycle initiation in yeast

SHILO *et al.*¹ have suggested that the transition probability model, devised to explain the regulation of proliferation of mammalian cells², can also be applied to yeast. They propose that traverse of an early G1 event called 'start'³ is probabilistic and is the rate-limiting step of the cell cycle. This suggestion arose from their investigation of the kinetics of bud emergence in cells released from a block at 'start', imposed either by using a strain conditionally defective in *cdc 25* or by using the mating hormone α factor. After release from a block at

Fig. 1 The kinetics of bud emergence according to Fig. 1 in ref. 1, replotted. The proportion of unbudded cells (ordinate) is plotted on a logarithmic scale against time after release of the block (abscissa). ▲, strain 352/1 (*cdc 25*) after release of temperature block; △, same strain after release of α factor block.

'start', the proportion of unbudded cells seemed to fall exponentially, indicative of a probabilistic traverse of 'start'. Unless the proportion of unbudded cells is followed to a low level, however, it is difficult to distinguish between an exponential line and the lines derived from other distributions of cell generation times, such as reciprocal normal (A. E. Wheals, personal communication). Of the six semi-logarithmic plots given by Shilo *et al.*¹ only one continues below a level of 10% of the starting value, and in this case (Fig. 1 in ref. 1) the line curves gradually downwards. There is also scatter of the points around the fitted exponential lines, particularly in Figs 2 and 4. Therefore the evidence in

favour of a probabilistic traverse of 'start' is not convincing.

Shilo *et al.* also suggest that the kinetics of bud emergence after release from a block at 'start' are the same as in a steady state culture, indicating that 'start' is the rate-limiting step in the cell cycle. This interpretation is only possible if the kinetics of bud emergence after release from the block are due solely to the traverse of 'start' and not to physiological recovery from the block. In the examples given this is not in fact so; although it is claimed that bud emergence shows similar first-order kinetics whether the block is imposed by α factor or by *cdc 25*, this only seems to be so because the data are on linear plots. If the data are replotted semi-logarithmically (Fig. 1), the lines can be seen to be different, the half life of the unbudded state for cells after release from the α factor block being 42 min, whereas after release from the *cdc 25* block, the half-life is 29.5 min. Corresponding transition probabilities (P values—see ref. 2 for definition) are 0.63 and 0.76 h^{-1} . Clearly the nature of the block at 'start' is affecting the kinetics of bud emergence, which nullifies any comparison with a steady state culture.

Interpretation of these experiments is further complicated by the use of *cdc 25*. Mutants in this gene are unusual as they stop growth at the restrictive temperature, unlike mutants in most other *cdc* genes⁴. For this reason Johnston *et al.*⁵ consider it likely that *cdc 25* is affected in intermediary or macromolecular metabolism and that its arrest before 'start' is only a secondary pleiotropic effect. If this is so then the experiment plotted in Fig. 2 only determines the kinetics of recovery from this block in metabolism and is not informative about the rate limiting step of the cell cycle.

Note added in proof: Variability in event traverse is not evidence for its rate-limiting nature unless it can be established that event traverse is probabilistic. Thus, knowledge of the exact kinetics of cycle initiation (see reply by Shilo *et al.*) is essential for determining whether 'start' is the rate-limiting step of the yeast cell cycle.

SHILO *et al.*¹ claim that their data support the concept of transition probability² in the yeast cell-cycle. However, evidence that fails to distinguish between two alternative hypotheses cannot be regarded as evidence in support of one of them. There are at least two contrasting models to account for the transition from an expandable part of the cell-cycle to a determined phase. The transition probability hypothesis argues that it occurs at random, there being a constant probability per unit time that a cell will undergo the transition^{2,3}. The cell size hypothesis suggests that cells monitor their own size and as they grow they undergo the transition when they have reached a critical cell size⁴.

Rate of entry into the budded phase is reported as showing first-order kinetics¹, but the measurements of the fraction of unbudded cells were not continued below 2%. Above these values there is virtually no measurable difference between first-order kinetics (α -curve), a lognormal distribution⁵ and a reciprocal normal distribution⁶ as can most clearly be seen when the same data are plotted equally successfully in quite different ways, for example HeLa cells^{2,7,8} and *Euglena*^{2,9,10}. Whereas first-order kinetics is consistent with the transition probability hypothesis, both lognormal and reciprocal normal distributions are consistent with critical cell-size hypotheses and the rate of entry could be interpreted as reflecting the heterogeneity in the size of the unbudded cells and the variation in time needed to grow to a critical cell size. Concomitant measurements of size were not made. Where this has been done, attainment of a critical cell size has been shown to be an important factor in the initiation of division in, for example, *Physarum polycephalum*¹¹, *Stentor*¹², *Amoeba*¹³, *Schizosaccharomyces pombe*¹⁴, and *Saccharomyces cerevisiae* (refs 15,16) and Wheals's unpublished data.

B. SHILO, V. SHILO and SIMCHEN reply
 —We believe that the asynchronous kinetics of cell-cycle initiation are a genuine characteristic of the 'start' process¹ and not an artifact of the methods used to arrest the cells². As shown in Table 1, five different haploid strains were arrested before 'start' by a variety of methods, including temperature blocks of the temperature-sensitive 'start' mutations *cdc 25*, *cdc 28* (ref. 3), *cdc 35* (L. H. Hartwell, personal communication) and *tra 3* (ref. 4), α -hormone arrest of *a* cells, and stationary phase arrest of cells at a high titre (4×10^8 cells per ml). In some of the treatments, cells were arrested for different lengths of time. In all cases, the half life ($t_{1/2}$) of the unbudded state after release from the block was in the range of 42 ± 13 min.

Fig. 1 Kinetics of bud initiation in an exponentially growing culture and following release from α -hormone block. The haploid strain A364A (ref. 3) is of mating type *a* and contains the markers *ade1*, *ade2*, *uia1*, *gal1-4*, *his7-1*, *lys2-2* and *trp1-2*. The cells were exponentially grown in YEPD medium¹ at 25 °C. They were slightly sonicated¹, diluted to 1.7×10^6 cells per ml and plated on YEPD medium solidified with 2% agar, at 25 °C. After plating, the % of unbudded cells in each sample was determined by counting at least 400 cells under the microscope. In the second experiment A364A cells were plated on YEPD solid medium following release from a 2.5-h block by a mating hormone¹. ■, Exponentially growing A364A cells after plating. □, A364A cells following release from an α -hormone block.

Table 1 Rates of release from blocks at 'start' and at a later stage (*cdc24*)

Strain	Mutation	Block type	Block period (h)	$t_{1/2}$ (min)
A364A	wild type	α -hormone	2.3, 2.5	32, 31
		Stationary	4, 4.8×10^8 cells per ml	42, 52
352/1	<i>cdc25</i>	36 °C	2, 3.3, 3.5	55, 43, 29
		36 °C	6	41
343	<i>cdc28</i>	α -hormone	2.5	39, 42, 50
		38 °C	3.8	41
353	<i>cdc 35</i>	α -hormone	2.5	38, 43
358	<i>tra3</i>	36 °C	3.3, 3.5	53, 38
337	<i>cdc24</i>	36 °C	2.8, 3, 3.3, 3.3, 4, 4.5	46, 53, 53, 10, 7, 10, 4, 9, 9

All cultures were grown in YEPD medium¹ at 25 °C prior to arrest and after release from the block. Each $t_{1/2}$ value was obtained in a different experiment.

This value is five times larger than the mean $t_{1/2}$ value obtained following release from a *cdc 24* (ref. 3) block, which comes after 'start'. The variation in $t_{1/2}$ values indicates that the physiological state of the cells, the block itself and the genetic background of the strain may have some effect upon the kinetics of cell-cycle initiation. But, these effects seem only to modify, not to generate, the asynchrony in cycle initiation. In extreme cases these effects result in physiologically deprived, or even non-viable cells, which remain unbudded for a very long time. We therefore feel that data on the initiation of the last 2% of the cells would not give reliable data on the kinetics of the entire population, as has been suggested^{2,3}.

To avoid the effects of the method of arrest on cell-cycle initiation, we have conducted an experiment in which budding was monitored in an exponentially growing culture of wild-type cells. It is known that a fraction of the unbudded cells in a growing culture is located between cytokinesis and 'start'. According to the "transition probability" hypothesis⁴ this fraction is expected to decline exponentially on plating on solid medium. This was indeed observed (Fig. 1), with the frequency of unbudded cells going down from 18% to 1%, according to first-order kinetics. Moreover, the rate-constant was very similar to that obtained with the same strain following removal of α -hormone block (Fig. 1). This experiment strongly supports the suggestion that first-order kinetics are a genuine characteristic of cell-cycle initiation.

The suggestion that *cdc 25* cells are arrested at 'start' as a secondary effect of a pleiotropic mutation⁵ is based only on the finding that they do not show any cellular growth at the restrictive temperature⁷. The latter observation can be interpreted differently, however. If the resting stage is just before 'start', we would expect cells to maintain a balanced physiological state as well as a constant cell size when arrested at 'start'. Following this rationale the *cdc 25* temperature block

is at the natural resting stage of the cell. Even if our interpretation of the *cdc 25* mutation is not accepted, it should be pointed out that the temperature-shift experiment (ref. 1, Fig. 2) was repeated with strains carrying mutations in either *cdc 28* or *tra 3*, that were arrested at the restrictive temperature, and with *cdc 25* cells that were arrested by α -hormone. Similar results were obtained in all experiments.

It has also been suggested that the asynchronous rate of cycle initiation results from different periods required by cells in the culture in order to reach a critical size⁶. The "transition probability" model⁴ and the "critical cell size" hypothesis⁶ are not mutually exclusive, however. We have mentioned¹ the possibility that the physiological condition of the cell could affect 'start' by imposing threshold requirements such as minimal size. Indeed, a recent report⁷ presents evidence suggesting that *Saccharomyces cerevisiae* cells must reach a minimal size in order to initiate the cycle at 'start'. We suggest, however, that heterogeneity in population size alone cannot be the reason for the asynchronous rate of cell-cycle initiation. After a cell reaches the critical size, initiation of the cycle is not an immediate consequence, but seems to depend on a random event. This suggestion is supported by the following experimental findings. (1) On release from a temperature block, the first buddings of the mutant *cdc 24* on solid medium appear synchronously (ref 1, Fig. 1). The second buddings are asynchronous, however, following similar kinetics to that of cell-cycle initiation with a $t_{1/2}$ value of 31 min. The theory of critical size cannot explain asynchronous budding of cells which have already produced at least one bud (and apparently reached the 'critical size'). (2) 'Start' arrest of *cdc 28* cells at the restrictive temperature, or *a* cells arrest by α -hormone, do not block cell growth, in contrast to *cdc 25* temperature arrest⁷. Similar kinetics of cycle initiation were observed in all three cases, however (Table 1).

In conclusion, we feel that the experimental data given here and in our previous publication¹ support the "transition probability" model⁶ for cell-cycle initiation, though admittedly additional variables may have to be taken into account. Discussions about the exact kinetics of cycle initiation, however, should not obliterate our main conclusion about 'start'¹, namely that it is the rate-limiting step of the yeast cell cycle.

Fission-track dating of pumice from the KBS Tuff, East Rudolf, Kenya

HURFORD, Gleadow and Naeser¹ claim to have fission-track dating results supporting the controversial 2.61-Myr value for the age of the KBS Tuff in East Rudolf, Kenya as determined by K-Ar dating²⁻⁴. The fission-track age does not, however, contribute substantially to solving this controversy, particularly since the authors¹ have not drawn attention to two important points, namely the error limits of the age and the current uncertainty about the spontaneous fission constant of uranium-238.

First, the quoted error of about 3% seems unrealistically small and probably represents only precision. The authors should give also the age accuracy which is necessary for comparing different radiometric ages. Second, many fission-track specialists no longer use the $6.85 \times 10^{-17} \text{ yr}^{-1}$ value, but now use as the decay constant $8.46 \times 10^{-17} \text{ yr}^{-1}$; there are good reasons for this preference⁵. If this higher value for the decay constant is used, the fission-track age of the pumice in the KBS tuff recalculates to 1.98 Myr, which would lend support to the K-Ar age measured by Curtis *et al.*³. For stratigraphic use of fission-track ages one has to be critically aware of, and draw attention to, the present uncertainty of the spontaneous fission constant of uranium-238.

NAESER, HURFORD AND GLEADOW
REPLY—We feel that the age we reported is a reasonable estimate for the age of the zircons separated from the pumice lumps in the KBS Tuff¹. If our age is wrong, it is wrong for reasons other than our choice of the decay constant² for the spontaneous fission of ²³⁸U. Two possible sources of error in this age are geologic in origin:

(1) The samples were collected in a sedimentary sequence. In this type of occurrence, contamination by detrital zircons is always possible and, in fact, is quite common. One advantage of the fission-track dating method is that the age of single crystals can be determined. A detrital zircon having an age greater than 10 Myr can easily be excluded from the population being dated. The problem occurs when the contaminating zircons are only a little older than the zircons being dated. The statistics of individual grains are such that a zircon having an age of 6 Myr would be included in the data because it cannot be reasonably separated from the rest of the population. In this case, however, five different determinations were made by three different individuals, and it seems highly unlikely that all three would choose the same relative numbers of contaminating grains. For this to happen, the detrital and pyrogenic zircons would have to be present in equal proportions, and the age of the detrital zircons could not be much greater than about 3 Myr.

(2) These zircons contained many small needle-like inclusions. Some of these could possibly have been counted as tracks, and this would result in an older age. As was true for the first source of error, this type of counting error would have to have been made by all three laboratories to the same extent.

Wagner² has questioned our choice of a decay constant, $\lambda_F = 6.85 \times 10^{-17} \text{ yr}^{-1}$ (ref. 3). When it is used in conjunction with the fission track glass standards of the U.S. National Bureau of Standards⁴, we get the best agreement with the K-Ar ages of co-existing minerals and we use it for this reason. This agreement has been found for minerals such as zircon, apatite, and sphene, as well as natural glasses that have not suffered track annealing. Figure 1 shows the results of 34 zircon fission-track ages plotted against the average K-Ar age of one or more minerals from the same rock. These ages are all from volcanic or sub-

Fig. 1 Zircon fission-track ages and the average K-Ar ages of minerals from volcanic and subvolcanic rocks. λ_F values $6.85 \times 10^{-17} \text{ yr}^{-1}$ (solid line) and $8.46 \times 10^{-17} \text{ yr}^{-1}$ (broken line).

volcanic rocks in which annealing should be absent or minimal. Alternatively we could have chosen an empirical method⁵ to calculate the ages of the KBS Tuff zircons. This method is independent of λ_F and neutron-dose calibration, simply requiring a number of samples from well-dated rocks. Had we chosen this method, our results on the zircons from the KBS Tuff would have been the same.

Wagner has also questioned our statistics². The precision of a single fission-track age determination is not equal to that of a K-Ar age, and probably never will be, but five separate determinations can produce a mean that has a reasonably small error associated with it. The accuracy of any age can only be guessed at, in that we do not know the true age of any geologic sample. We can only strive for the best agreement with K-Ar and the other dating methods.

We therefore think that our age of 2.4 Myr is a reasonable estimate of the age of zircons separated from the pumice lumps present in the KBS Tuff. If Wagner feels that we must use $\lambda_F = 8.4 \times 10^{-17} \text{ yr}^{-1}$, then he must show us where we have a corresponding 20% error in our method that compensates for our choice of decay constant and that will account for our close agreement with K-Ar ages.

Southern oscillation index and atmospheric carbon dioxide

BACASTOW¹ claims that the Southern Oscillation (SO) modulates atmospheric carbon dioxide, which may be true, but was not proven by his article.

Bacastow compared a SO index with both carbon dioxide concentrations and its time derivative. In his Fig. 1 carbon dioxide concentrations were smoothed in an unspecified manner. Taking the derivative is equivalent to applying a high pass filter to the data and results therefore depend on the original smoothing. With different forms of smoothing applied to each series the phase relations will be affected.

The period of data used in the study was from 1958 to 1974, which includes the period 1960–1965 when the SO was not operating effectively. Trenberth² shows that, in the early 1960s, the correlations of pressure between Easter Island and Darwin—required by the SO mechanism to be negative—were in fact positive. He further shows that the SO operates only on a time scale of 2–10 yr and mainly in the 3–6-yr range. Marked quasi-biennial fluctuations occur at Darwin, but not Apia, Tahiti, or Easter Island in the South Pacific. The quasi-biennial oscillation and the SO are not apparently the same thing, although they may interact at times. Furthermore, lags of up to 1 yr are involved in the opposite changes at Darwin and Easter Island³.

Further consideration should therefore be given to the choice of a SO index. Trenberth suggests that a simple index involving only Darwin and Tahiti would

Table 1 Southern Oscillation index correlation with CO₂ data

Derivative anomaly	SO index	Smoothing	Correlation maximum	Anomaly lag (month)	Standard deviation
South Pole	$P_{EAS} - P_{DAR}$	12 month running mean	-0.64	6	0.34
Mauna Loa	$P_{EAS} - P_{DAR}$	12 month running mean	-0.55	2½	0.28
South Pole	$P_{UAS} - P_{DAR}$	Spline	-0.70	6	0.36
Mauna Loa	$P_{EAS} - P_{DAR}$	Spline	-0.56	2½	0.31
South Pole	SO1	3 month running mean	-0.60	4	0.26
South Pole	SO2	3 month running mean	-0.59	4	0.24

P_{EAS} and P_{DAR} , seasonal pressure anomalies at Easter Island and Darwin respectively.

be best since these stations have the highest negative correlation (-0.76 for yearly values for 1944–73) and are almost exactly out of phase. This could be used to define lag relationships elsewhere. Seasonal, rather than monthly data should be used.

To find such an index, we note that an exact inverse correlation between Darwin and Tahiti, using their standard deviations gives

$$P_{Darwin} = -1.26 P_{Tahiti} \quad (1)$$

where P is the seasonal pressure anomaly. Since part of the mass compensation from the Indonesian centre of action of the SO occurs south of Australia and New Zealand as well as in the South Pacific³, greater weight should be given to the pressure at Darwin in a SO index (see Fig. 6 of ref. 3). A suitable weighted index, based on covariances, is

$$SO1 = P_{Tahiti} - 1.2 P_{Darwin} \quad (2)$$

As only two stations are included, some noise would be present, but is measured by

$$SON = 1.26 P_{Tahiti} + P_{Darwin} \quad (3)$$

which from (1), has a zero value if the SO is operating.

An index that combines (2) and (3) is

$$SO2 = \frac{P_{Tahiti} - 1.2 P_{Darwin}}{1 + |SON|} \quad (4)$$

I suggest that this index may be more useful than any previously used.

³ Kidson, J. W. *Mon. Wea. Rev.* 103, 187–196 (1975).

BACASTOW REPLIES—Trenberth is correct in pointing out that different filtering of two time series will, in general, affect their correlation–time lag relationship. I do not believe, however, that this consideration is important in judging the existence of a connection between the Southern Oscillation (SO) and the atmospheric CO₂ level. If a Southern Oscillation Index is generated by smoothing the Easter Island–Darwin, Australia, pressure differences by the procedure applied to the CO₂ data, the cross correlation functions of this index with the time derivatives of the CO₂ anomalies (see Table 1 for summary) are essentially the same as found for these pressure differences smoothed by a 12 month running mean.

The mechanism behind the SO is poorly understood, so the best index to represent it is unclear. The indices suggested by Trenberth (calculated from data in ref. 1) are qualitatively quite similar to the Easter Island–Darwin Index, except for the obvious difference in degree of smoothing (Fig. 1). Pressure anomalies were smoothed by a 3-month running mean, in accordance with Trenberth's suggestion that seasonal data be used. Cross correlation functions of SO1 and SO2 with the CO₂ anomaly derivative at the South Pole (Table 1) are very similar to those found for the Easter Island–Darwin Index, except that the lag of the anomaly is about 2 months less relative to the Tahiti–Darwin indices, as would be expected from the analysis of Trenberth².

Fig. 1 Southern Oscillation indices. *a*, Differences in monthly average pressure between Easter Island and Darwin, Australia, smoothed by a 12-month running mean (which also removes the seasonal effect). *b*, Pressure differences above with the seasonal effect removed. The curve is a spline obtained by the procedure used to find the CO₂ anomalies, and, accordingly, the stiffness of the spline was adjusted by eye. The seasonal effects were calculated by an average over identical months of the difference between the pressures and the spline. *c*, SO1. The seasonal effects at Tahiti and Darwin were determined by an average over identical months of the monthly average pressure records (since 1950) and removed from each record by subtraction. Each record was then smoothed by a 3-month running mean and SO1 calculated. *d*, SO2. *e*, Inverted time derivative of the South Pole anomaly, for comparison.

reviews

Disaster book

Peter J. Smith

Forces of Nature. Edited by Sir Vivian Fuchs. Pp. 303. (Thames and Hudson: London, 1977.) £9.50.

PERHAPS UNWITTINGLY, this book plays a small part in a curious paradox. For the past few years the world economy has been in recession, human institutions have been under threat as seldom before, and the general feeling has been one of gloom and despondency. But as if that were not enough, the same period has seen a remarkable upsurge in the publication of books about those macroscopic forces of nature which can, and do, contribute to recession, destroy human institutions and give rise to gloom, not to mention real hardship. The level of interest in earthquakes, volcanic eruptions, drought, floods, avalanches, tornadoes and forthcoming ice ages has recently reached a new height and shows no sign of falling. It is almost as if we were trying subconsciously to diminish the relative force of human mismanagement by pointing to greater events beyond our control.

But if so, we are doomed to failure, for what Sir Vivian's book tells us time and again is that in the face of disruptive natural forces human folly is only magnified. The ancient city of Antioch was repeatedly destroyed by earthquakes and equally repeatedly rebuilt on the same site with similar materials and no more effective rules—a self-defeating activity which even the most highly developed nations have been unable to avoid. In 1963 the Vaiont reservoir in Italy overflowed violently with the loss of 2,600 lives, because no-one had read the lessons plainly visible in the local history of landslides. In Switzerland the obvious dangers of avalanche are often ignored even by experienced mountaineers. In countries where drought is endemic, populations grow unchecked, making each disaster more devastating than the last. And so on.

Under the circumstances it is perhaps understandable that Sir Vivian should take a dim view of human capability. Of all the forces of nature, he suggests in his introduction, "none can be controlled by human agency. Even if our growing knowledge was to make this possible, it is doubtful if we have, or could acquire, the wisdom to handle

them for the general good . . . It may well be wiser to accept the broad interplay of natural forces, always learning better how to use them or to protect ourselves from them." Not everyone would agree with that, regarding it as overly defeatist, for the reference to protection reminds us that man is not entirely incapable of fighting nature. From the Tennessee Valley Authority (for all its faults), through splitting wedges in the Alps and the sea wall at Skegness, to the person who decides that Denver offers a safer life than Los Angeles, there is ample evidence that nature needed not always win.

In *Forces of Nature*, each chapter of which is written by "an expert in his field", man's attitudes and responses to natural phenomena are given more than usual attention, although firmly set against a background of scientific explanation. The blend of science and sociology works well, leading to a nicely balanced text that should have wide appeal. What ultimately makes the book, however, is less the text than the remarkable collec-

tion of photographs (researched by Sarah Waters), some in black-and-white but many in colour.

And therein lies something slightly unnerving. For the truth is that in the hands of a brilliant photographer, and with a magnificent standard of reproduction, the consequences of the most devastating natural disaster may be recorded as something of astonishing beauty. The funnel of a tornado crossing Oklahoma, a parched and drought-cracked river bed in Kenya, rooftops projecting from a major flood near Brisbane, the distortion of a flood-swept railway line in the Netherlands, and molten lava from Etna advancing towards civilisation, must all have represented absolute despair to someone; and yet on the page they make pictures as enticing in their way as a *Hay Wain* or a *Fighting Temeraire*. It's all vaguely disconcerting, but makes for a fascinating book. □

Peter J. Smith is Reader in Earth Sciences at the Open University, Milton Keynes, UK.

Time problems in land processes

Geomorphology and Time. By J. B. Thornes and D. Brunsden. Pp. 208. (Methuen: London, 1977.) Hardback £6; paperback £3.45.

WHAT George Poulett Scrope wrote in 1858, that "the leading idea which is present in all our researches, and which accompanies every fresh observation, the sound which to the ear of the student of Nature seems continually echoed from every part of her works, is—Time! . . . Time! . . . Time!", could be equally well be applied to studies today. It was the geologist who discredited the rigid biblical timescale and extended the overall limits of earthly time from under 6,000 years to over 4,000 Myr. Geomorphologists joined the geological bandwagon with one hand on the leading rein. Quite early they began to be interested in rates of processes, and eventually acquired an assortment of morphological measurements and crude timescales

for the effects of denudation and deposition on landforms.

Being concerned with present processes, geomorphology has contemporary utility, and the hope has always been that the present would also provide a key to the past. This is of course, true of the action of processes and untrue of landscapes. In any event, time-independent processes cannot exist. So time is a necessary ingredient of geomorphological research and must be considered with other essential features such as lithology, process and spatial variability, all of which impinge on problems of scientific observation, model-building and interpretations of the temporal occurrence of events.

The authors of this book elucidate these ideas on time in a lively introduction which treads warily around many pitfalls and will stimulate much thought. For example, we are told that velocity is expressed as distance moved in unit time (L/T). This seems reason-

ably applicable to large deep rivers, but I wonder if, in fact, in steep shallow channels with rocky, pot-holed beds, where some water movement is uphill, geomorphologists do measure the true distance travelled by a water particle in a given length between two successive points. Among the many interesting topics mentioned in these introductory pages are relaxation time and feedback in energy systems.

The following chapter discusses at some length the criteria that Earth scientists use to obtain a chronology. Relative morphological vertical position, extent of drainage patterns, stratigraphy, mineral and organic content, weathering, artefacts, radiation, tree rings and lichenometry all find a welcome place, but thermoluminescence might perhaps have been better replaced by palaeomagnetism. The discussion then proceeds to the measurement of variables in time, the analysis of temporal data, and the rates of operation of geomorphological processes. In these the authors rightly consider that awareness of techniques will make the reader more careful in designing experiments for the collection of time-based data and more aware of the inadequate nature of much of the published data on measured rates of processes.

Collagen biochemistry and biophysics

Biochemistry of Collagen. Edited by G. N. Ramachandram and A. H. Reddi. Pp. xv+536. (Plenum: New York and London, 1976.) \$59.40.

UNTIL some 30 years ago, collagen was of interest mainly to industrial chemists concerned with the properties of leather, glue and gelatine. Since then, there has been a rapid expansion of information concerning collagen structure, metabolism and function. This book, as the title implies, covers the biochemistry of collagen but also contains chapters more properly labelled biophysics.

The chapter by Piez collates the information available on the primary structure of collagen polypeptide chains. Also discussed are the sequences involved in the unique post-translational modifications, particularly hydroxylation and crosslinking. There are brief descriptions of the methods of isolation of the different collagens and of the polypeptide fragments to which the usual methods of sequencing have been applied.

The next three chapters of the text provide information on the various types of models concerned with the way that events change in time. The qualitative temporal variety leads on to the quantitative deterministic type and so to the less certain stochastic models of form evolution. Not surprisingly, as geomorphologists deal with area realities, there follows a discussion on the setting of events or points into a framework wherein spatial characteristics or patterns evolve. A summary of space, and time and a long bibliography of mainly post-1960 literature, form a suitable conclusion.

In brief, this neat and well-illustrated book provides at a reasonable price a commendable introduction to recent conceptual advances in time-related factors in geomorphology. Geomorphologists may have far to go and some time to wait before their recordings on rates of process become truly reliable but this excellent summary will provide students with a clear view of the time-scale aspect of present achievements.

Robert P. Beckinsale

Robert P. Beckinsale is an Emeritus Leverhulme Fellow and a Special Supernumerary Fellow of University College, Oxford, UK.

The chapter by Ramachandran and Ramakrishnan provides a general account of the early X-ray diffraction studies which led to the formulation of a triple-helical structure for collagen, together with a more detailed consideration of recent modifications of this basic structure. The chapter on synthetic polypeptide models is largely redundant, much of the material being covered by other authors.

The molecular packing of collagen monomers in fibrils is the subject of a chapter by Miller who discusses critically the methods available for studying this packing, particularly X-ray diffraction and electron-microscopy, and the results obtained by these techniques. More tentatively, he discusses the possible models which can be derived from the data available.

The complex processes by which the collagen molecule is synthesised are dealt with by Prockop and his colleagues. After a short section on collagen mRNA, the manifold post-translational modifications which the primary structure of collagen undergoes are discussed. These include hydroxylation of lysine and proline, and glycosylation of hydroxylysine. Also discussed is the final intracellular process which involves the assembly of three polypeptide chains and the subsequent triple helix formation before the

molecule is secreted. The final section is a stimulating discussion of the regulation of these intracellular processes by which the wide range of chemically different collagens found in the body are achieved.

After secretion the completed molecule is cleaved to form a molecule which can form a fibril by a process of self-assembly. The stabilisation of the fibrillar structure by covalent crosslinks is discussed in a chapter by Tanzer. This deals with the structure and mechanism of formation of these crosslinks.

The enzyme mammalian collagenase, one of several proteases involved in collagen degradation, is the subject of a very useful chapter by Gross. The most interesting section is that concerned with the regulation of collagenase activity and how it is synchronised in time and space with collagen biosynthesis.

The chapter by Timpl on immunological studies is concerned with the diversity and localisation of antigenic determinants on the collagen molecule. There are useful sections on the use of specific antisera to detect anticollagen antibodies and also as tools to study the structure and metabolism of collagen. There is a section on the use of fluorescent collagen antibodies to localise and follow the temporal changes in the appearance of the different genetically determined collagen.

The molecular basis of diseases affecting collagen is dealt with in an excellent chapter by Lapière and Nugens. This contains two tables of data on the cellular and molecular basis of collagen defects, and on the techniques applied to define collagen pathology. Various diseases of connective tissue, both inherited and acquired, are discussed in the light of current knowledge of collagen structure and metabolism.

The chapter by Reddi is somewhat disappointing. It covers rather sketchily an area of research concerning the intimate involvement of collagen in cell differentiation and organogenesis. This is an important topic requiring a more detailed and critical review than that provided by this chapter.

There is evidence of a considerable gap between the completion of the manuscript and final production of the book (compensated in some chapters by addenda). Nevertheless this is a reasonably up-to-date account of the current status of collagen research which should be useful to workers in a wide variety of disciplines.

D. S. Jackson

D. S. Jackson is Professor and Head of Department of Medical Biochemistry at the University of Manchester, UK.

Ecological parasitology

Ecological Aspects of Parasitology. Edited by C. R. Kennedy. Pp. x+474. (North-Holland: Amsterdam and Oxford, 1976.) Dfl 145; \$57.95.

PARASITISM is an ecological term, and parasitology is essentially an ecological study. Some aspects of parasite ecology have received extensive coverage for many years, especially those related to qualitative and quantitative epidemiology, where the unit of study is the infection rather than the parasite.

The stated object of this book is to remedy the situation whereby some aspects have received little attention. The aspects chosen in the first section concern the parasite outside the host: dispersal (C. R. Kennedy), host location (A. J. MacInnis) and host selection (J. C. Holmes); entry into the host (D. W. T. Crompton), feeding (C. Arme), interaction between parasites (D. Halvorsen), and host responses to parasitic infection (D. Wakelin). The bulk of the book is in part two. Here, "Habitat" is seen as the immediate surroundings of the parasite. There are two chapters on fish: skin (G. C. Kearn) and gills (C. H. Fernando and C. Hanek); and the remaining chapters deal with the special features of parasitic life in different mammalian or avian organs and cells. In the final chapter, R. M. Anderson discusses the interaction of host and parasite populations.

With 24 authors covering so wide a field, consistency and uniformity are not to be expected or even desired. If the intellectual verbosity of chapter one were maintained throughout, the book would be hard indeed to read. Particularly noteworthy is yet another definition of parasitism, first credited with elegant beauty, then, mercifully, discredited as being possibly applicable to all organisms!

The rest of the book is clear and stimulating. The only truly unique feature of the parasitic habitat is the specific antagonistic reaction that it produces. This aspect is given extensive treatment. D. R. Arthur describes how amputee mice, unable to groom, are subject to massive infestations of lice; D. Wakelin gives a lucid comparison between the immune processes of invertebrates and vertebrates, and A. D. Befus and R. B. Podesta describe the special immunological features of the intestine.

Most other aspects of parasite ecology have clear parallels in free living organisms. Useful comparisons are made but unfortunately not ex-

panded with both sessile and planktonic marine animals. More such comparisons could have been enlightening.

The great value of this book lies in the descriptions of various organs from a parasitological viewpoint. Almost every author points out areas of extensive ignorance in his field, and it is clear that too few physiologists, biochemists and physicians have a clear idea of what ecology is about. The book will surely be useful as a

stimulant for discussion and further investigation. It is a little disappointing that in so extensive a series of reviews there is a sad lack of coordinating thought. Perhaps, though, that is what the book will help to produce.

R. W. Ashford

R. W. Ashford is Senior Lecturer in the Department of Pathology, University of Papua, New Guinea, on secondment from the Liverpool School of Tropical Medicine.

Electron theory of small molecules

Introduction to the Electron Theory of Small Molecules. By A. C. Hurley. Pp. 329. £12; \$26.25. *Electron Correlation in Small Molecules.* By A. C. Hurley. Pp. 276. £10.50; \$23. (Academic: London and New York, 1977.)

THESE two books are perhaps meant to be read together. The author states in his preface to the *Introduction* that the book consists of the "earlier and simpler chapters of what was originally conceived of as a comprehensive one-volume work". As such, the *Introduction* is to provide what the author calls a "royal road from basic quantum mechanics to the various theories which are now yielding such detailed information on molecular interactions", some of which are discussed in the *Electron Correlation* volume.

The *Introduction* provides an account of the basic theory of potential energy curves and surfaces, an outline of the variational method for constructing approximate electronic wave functions and a short account of the (generalised) virial and Hellmann-Feynmann theorems. It also provides a brief, but self-contained account of molecular symmetry and quite extended accounts of the determinantal approach and of molecular orbitals and the Hartree-Fock method. The accounts are presented chiefly in the context of results for diatomic molecules (although small polyatomics occasionally receive a passing mention) and a chapter each is devoted to detailed consideration of the hydrogen ion and of the hydrogen molecule.

The book is regrettably something of a disappointment to the reviewer, if for no other reason than that it seems so old-fashioned. A suspicion of this may be gleaned from the first few pages in which it becomes clear that the author is going to use c.g.s. units; but it is re-inforced, for example, by his treatment of spin-coupling and of methods for solving the SCF equations,

for which he gives no references more recent than 1967. Indeed, if one looks through the text one gains the impression that the phrase "recent work" should really be synonymous with "ten-year-old work". This criticism should not, of course, be construed as a call for "trendiness", but there is work in the past five years in the areas quoted above (and indeed in other areas in the book) to which the attention of the reader should be called even in an introductory book like this.

As one would expect from an author of Dr Hurley's distinction, there are a lot of good things in the *Introduction*. There is, for example, a splendid and precise account of Koopmans' theorem, a very nice heuristic account of the various cusp conditions in the wave function, some very helpful material on the continuous groups in the section on symmetry, a brief and clear account of the RKR method, and many more. There are, however, some funny slips. The author says, for example, that in the quadratic approximation to the potential, the equation for nuclear vibrational motion in the diatomic is the simple harmonic oscillator equation. But the student who has read his Eyring, Walter and Kimball *Quantum Chemistry* knows that this is just not true. The equation (2.60) from which he begins his account of the generalised Hellmann-Feynmann theorem seems to be simply wrong at an elementary level (see the author's own original paper, *Proc. R. Soc. A* **226**, 170 or Appendix 1 in Pople *et al. J. Chem. Phys.* **49**, 2960; 1968), and in view of Dr Hurley's contributions to the foundations of this part of the subject this (if the reviewer is not mistaken) is quite incredible. Be that as it may, the discussion in this part of the book has nothing like the subtlety or power of the discussion of the same material offered by Epstein in his recent book (*The Variation Method in Quantum Chemistry*, Academic: London, 1974); and Epstein's book is not referred to at all.

At a somewhat different level, the author's discussion of natural orbitals

(continued on p654)

will strike the initiated reader as very eccentric; and I do not think it will help the beginner. The index of the book also seems to have its eccentricities. If one looks up "charge density" for example, one gets referred to two pages on neither of which is the concept defined or anything other than incidentally mentioned. One does not get referred to the section on p303, which has charge density in its heading, which is perhaps just as well because the section contains no mention at all of the idea.

The book cannot therefore be recommended unreservedly as an introduction to the field but it is nevertheless a book that repays careful reading and should be useful to those teaching advanced undergraduate and graduates in the subject, if only because there is not really another book in this area.

Electron Correlation consists of just two chapters, one entitled "First Order CI and VB methods" and the other (about 200 pages) "The Correlation Problem". Again, the emphasis is on diatomics but polyatomics get a better look in than in the *Introduction*. The underlying and unifying theme of the book seems to be designing wave functions for molecules which correctly describe their dissociation into fragments. In the first chapter the author takes a rather eclectic view of CI and VB, and the reader looking for detailed accounts of the current state of the art in these methods will be disappointed. In fact most of the chapter is devoted to a discussion of symmetry principles, of a particular multi-configuration SCF method and of an introduction to the theory of separated electron pairs. The second chapter is devoted almost

entirely to pair theories culminating in an account of the coupled pair approximation treated in a manner equivalent to Cizek's treatment. After a short discussion of the requirements necessary to obtain chemical accuracy using such methods the chapter ends with a brief account of putting r_{12} explicitly into the wave function particularly by the *trans*-correlated method.

Once more there are lots of good things in this book. There is a splendid account of natural spin-orbitals and the convergence of the CI expansion, and of the difficulties in iterative pseudo-natural orbital approaches. There is a very clear and precise account of the deficiencies inherent in particular classes of wave functions constructed from strongly orthogonal groups. Indeed, the whole account of development of pair theories is clear, coherent and precise, and extremely well illustrated by results from actual calculations.

Again it does seem to lack references to more contemporary work: obvious omissions are the work of Meyer and that of Ahlrichs and his group in the pair function field. One would also expect to see more references to recent work in the CI and VB approaches. The result is that the book must strike the informed reader as a somewhat unbalanced account of the field.

The reviewer's reservations here are, however, only minor. *Electron Correlation* is a book that many practising quantum chemists will surely want to own.

Ice Age, ancient and modern

The Ice Age: Past and Present. By Brian S. John. Pp. 254. (Collins: London, 1977.) £4.95.

ADDING to the rapidly expanding recent literature on glaciers, Ice Ages and such topics, Brian John has produced a useful non-technical volume that is designed to appeal to "the person who knows very little about ice and glaciers and even less about the Ice Age". In 235 pages it covers a great deal of ground, from how glacier ice is formed to its effects on the Earth's surface, from ancient Ice Ages to speculative comments on future climatic change. Inevitably the treatment becomes somewhat superficial in places, as when the botany of the Ice Age is surveyed in just 12 pages; but on the whole it

succeeds very well in dealing with such a huge canvas. Moreover, it is a soundly based book: on geomorphological and geological aspects, John knows his stuff, and therefore unlike many popular or semi-popular accounts, the text is reliable and up-to-date.

The arrangement of material is clear and logical. The first half of the book looks at the nature and origins of glaciers, their effects on landforms through erosion and deposition, the landscapes associated with both continental and alpine types of glaciation, and the work of glacial meltwater in washing out and transporting debris away from the edge of the ice. There follow short chapters on ice in a periglacial environment, touching briefly on permafrost, frost weathering, patterned ground, pingos and other ground-ice features, and on sea ice, dealing with ice shelves, pack ice and icebergs.

The second half of the book deals mainly with Ice Ages. Sensibly, for

this type of book, John begins with the recent historical past, discussing the effects and significance of the "Little Ice Age", before delving further into the past to consider the Pleistocene period and then the pre-Pleistocene glaciations, as well as the innumerable theories of the causes of Ice Ages. There is an outline of the effects of glaciation on land and sealevels; a minor criticism here is that *non*-glacial causes of changes in level tend to be ignored so that one gets the erroneous impression, for instance, that the sinking of the North Sea basin is somehow bound up with glaciation. Three chapters provide brief summaries of Ice Age plants, animals and man, and the book concludes with a discussion of what the future may hold in store—when will the present interglacial come to an end, how will it end, and what impact is man having on the world's glaciers, intentionally or unintentionally?

Throughout, John tries to write in a simple non-technical style. On the whole he probably succeeds in making the subject matter intelligible to the non-specialist, but often at the risk of over-simplification. At times, however, he lets his imagination run away with him. Such statements as "You don't have to ask an Eskimo whether we are living in the middle of an Ice Age", or "Like the Irish navvies of Victorian times, the most active glaciers tend to be the most efficient, and where they have plenty of excess energy they achieve prodigious feats of erosion and transportation", are probably acceptable in a book of this sort, but some other passages draw rather far-fetched similes. Did he really have to write that "Unstable glaciers cannot find relief from the stresses of life by weeping or getting drunk", or that "Pingos prefer to live in groups . . ." (they are described as "lovable creatures" because they tend to cluster together)?

The book is well produced with few errors. An amusing slip is 'subsiding' instead of 'subsiding' on p230. The 32 half-tone plates are mostly of high quality (the ERTS imagery of Skeidararsandur is an exception), and the line-drawings are clear. The latter, oddly, are not numbered and not specifically referred to in the text. There is a short list of books for further reading, and an index. At £4.95, the book represents reasonable value for money; it ought to attract the non-specialist reader and it will certainly stimulate the intelligent sixth-former (advanced school) student to find out more about ice and Ice Ages.

Dismantling the firebreak

RESEARCH and development of tactical nuclear weapons has been conducted for many years now with relatively little public debate against a background of even less public information. So it would be unfortunate if the recent revelation of budgetary proposals for 'enhanced radiation' devices to be built by the US Energy Research and Development Administration were to be seen only as a step, and maybe not a very big one at that, towards a new type of weapon. For the whole question of tactical nuclear weapons, regardless of their mixture of blast and radiation content, deserves a much wider airing.

Tactical nuclear weapons have yields of the order of tons rather than the kilotons or megatons of strategic devices. They can be fired from tanks as shells; and as miniaturisation proceeds they are more easily adapted to mortars or even suitcases. Enhanced-radiation/reduced-blast tactical devices would carry the added attraction for the field commander that the area bombarded would not be so devastated and full of radioactive debris as to be inaccessible subsequently to his own troops. So an enhanced radiation device would be ideal for land battles where territorial advantage counted.

Not so ideal, however, is the way recent developments in nuclear weapons have been closing the gap between

conventional explosives and strategic nuclear weapons. Until the late 1960s there was a very clear firebreak between the limited damage that chemistry could inflict and the devastation that physics could wreak. Soldiers could be entrusted with conventional weapons, but only presidents could launch nuclear devices. Then to bridge this gap came tactical weapons that were scaled down strategic weapons.

Now the talk is of devices that cause even less damage but kill more, and they are beginning to look distinctly like biological weapons. Advocates of the new devices still see firebreaks to prevent a limited confrontation from escalating into an all-out nuclear war, but this is a very optimistic point of view and assumes that belligerents will recognise each other's devices for what they are, have no wish to respond more aggressively and have the right weapons available to permit response in kind. It's a tenuous line of argument to say the least, and many will find it totally unconvincing.

In the past 25 years an immense amount of thought has been devoted to the possibilities of restricting strategic armaments. The need now is for some equally intensive studies to be made of ways of averting the escalation which new weapons technology is making progressively more likely. □

Dissecting the crisis

RECENTLY the European Commission, the EEC's administrative-cum-executive arm, sponsored a colloquium in Brussels entitled 'Crisis of science in European societies?' Everyone who attended seemed to take it for granted that the answer to the question is 'yes'. But though that may be right, the crisis borne of the modern problems of the bomb, the environment, energy, resources and changing social attitudes has been around for some years now. And crises, like lost tempers, should be over quickly if they are not outward signs of something more serious.

The Brussels symposium could hardly have been said to have come to grips with this deeper problem, beyond revealing that there are different opinions and judgments about what should be done. For some this may be suf-

ficient—a symbolic meeting of cultures, an agreeable renewal of old friendships, may be all they sought from such a meeting. They might even see it as pretentious to claim that gatherings like these could go further, though just such hopes were being entertained.

But there is meanwhile a real and deepening problem for many scientists. It involves falling funds, less research and fewer researchers. And it highlights what is perhaps the most serious problem to be faced: that scientists, unlike most other discernible groups, do not seem able to organise themselves to talk plainly to governments. Nor for that matter does the decision-making system encourage such organisation. Amiable gatherings in Brussels are a poor substitute for hard talking nearer home. □

Too late not to proliferate?

David Fishlock examines the background to the burgeoning international trade in nuclear technology

DR Glenn Seaborg, the chemist who with E. M. McMillan first isolated plutonium, delivered a paper on "the plutonium economy of the future" in Santa Fe in 1970. It was an important paper; Seaborg, as chairman of the US Atomic Energy Commission, was forecasting that by 1990 one-quarter of the energy used by the USA could come from plutonium. By then, he said, the nation would have accumulated a plutonium stockpile from its light water reactors worth (at 1970 prices) about \$6,000 million—twice as much as the US investor-owned utilities had spent on fuel in 1969.

The paper attracted little attention. The campaign against nuclear energy in the US, although well under way, was almost wholly engaged in attacking the intrinsic safety of nuclear reactors. Proliferation of nuclear materials, although a subject of deep concern to a great many governments, was not a public issue, much less a target of anti-nuclear campaigners. Neither were nuclear weapons or nuclear materials then seen as serious targets for international terrorists.

By the mid-1970s, however, the anti-nuclear campaigners badly needed a new target. Although they had succeeded in slowing the pace of licensing and construction of reactors, they had failed completely to make out a case against them as a potential hazard. Not a single nuclear plant had been shut down because it was emitting, or was considered liable to emit, dangerous amounts of radiation.

Plutonium, and plans to refine and recycle it, and to use it to fuel more advanced types of reactor, offered a tempting new target. The very name of the element, its "fiendishly toxic properties" as one US physicist had once described them, and its immense potential as an explosive offered clear advantages in arousing public fears. Overnight the 'plutonium economy' became a catchphrase depicting a world unfit for human beings.

Three events

Three events contributed importantly to the widespread fears now aroused about the plutonium economy and its implications. The first, in May 1974, was the explosion by India of a plutonium device it euphemistically referred to as a "peaceful nuclear explosive". This was a profound shock

for those nations which for nearly 20 years had been striving for international controls on the use of nuclear technologies. In public India had declared repeatedly that it would never make a nuclear weapon. So, in spite of the fact that India had been opposed from the outset to any idea of international control and safeguards through the UN's International Atomic Energy Agency (IAEA), such nations as the US and Canada had provided India with nuclear technology and know-how, sometimes on very generous terms. Under the Colombo Aid programme Canada provided an NRX research reactor free from international safeguards. The Indians used this reactor to transmute natural uranium into plutonium.

The second event occurred about a year later, in the summer of 1975, when after some months of publicity the West German Government signed a contract with Brazil to provide that country with virtually a ready-made nuclear industry, including the technology to separate plutonium and to enrich uranium. It was the biggest nuclear export contract any country had ever won. But the US Government had already turned down Brazil's requests for enrichment and reprocessing, not least because Brazil refused to sign the 1969 Non-Proliferation Treaty (NPT).

The furore over the German-Brazilian contract also highlighted a number of other nuclear contracts under negotiation, notably contracts under which France planned to provide Pakistan and South Korea with reprocessing plants. Together with the Indian explosions, these negotiations prompted the US Government to bring together for the first time the seven leading nuclear supplier nations at a secret meeting in London to try to find more effective controls for the transfer of 'sensitive nuclear technologies'. These were then defined as the technologies of reprocessing and enrichment, both of which could be adapted to yield fissile materials, and the production of heavy water.

The third event of importance in establishing the plutonium economy as a public issue was the publication in September 1976 of the Sixth Report of the Royal Commission on Environmental Pollution, under the chairmanship of Sir Brian Flowers. In spite of the fact that Flowers had never once raised the matter as a part-time mem-

ber of the UK Atomic Energy Authority, this report expressed deep concern with the idea of any plutonium falling into the hands of terrorists. If the stability of our society continued to deteriorate, it suggested, proliferation of the sources and movements of plutonium could begin to pose a serious hazard.

Meanwhile the US Government had been abruptly awakened to the fact that it was fast losing control of technologies it had sought to control—for example, through its patronage of the IAEA and its domination of the enrichment and reactor markets—since the end of the Second World War. It searched desperately for fresh safeguards against proliferation. Dr Henry Kissinger, as Secretary of State, enthusiastically endorsed an IAEA idea for regional fuel cycle centres operating under international management and safeguards to serve such areas as Latin America and the Middle East with 'sensitive technologies'. A major study by the IAEA soon disclosed that while the regional concept was politically impractical—it was difficult to conceive of a project or a site that would serve Brazil, Argentina and Chile, for instance, or Egypt, Israel and Iran—the multinational reprocessing centre was a serious proposition. Where the centre was located was of small importance since transport costs varied little with distance. But economies of scale made the economic advantages of large plants attractive to any nation with purely commercial aims. The IAEA concluded that ideally a multinational reprocessing centre would be set up by five or seven nations, one or more of which would be able to provide the technology and organise the financing of plants expected to cost of the order of \$1,000 million. Such a centre would justify full-time surveillance by IAEA inspectors to ensure that no illegal diversion of plutonium took place.

Interest waned

Promising as the outcome of this study proved to be, the interest of the US Government had waned long before its formal presentation at the nuclear conference in Salzburg next month. At best it could be a medium-term solution, for such centres would need at least a decade to organise and bring into service. Even the technologically simpler problem of organising international plutonium storage might take a decade to bring about. The US was urgently searching for tighter controls against proliferation that could be implemented here and now.

Its response came finally in a statement on 7 April in which President Carter formally declared a moratorium on one of the sensitive technologies,

reprocessing. In future the US would store the highly radioactive fuel from its light water reactors. The president took care at this time to stress that this was domestic US policy for controlling proliferation, and that it recognised that other nations with no indigenous uranium might not be so willing to forego the uranium and plutonium locked up in spent fuel.

During the month that followed two further aspects of US anti-proliferation policy emerged. One was that in order to try to persuade other nations to follow the US policy, America was going to expand her uranium enrichment capacity while still keeping this activity firmly under government control. The implication was that it was prepared to supply enriched uranium from its own reserves, enriched to the low level required in existing thermal reactors, and moreover would be prepared to store unprocessed spent fuel for customers.

What also emerged, in a statement from Dr Joseph Nye, a senior State Department official concerned with anti-proliferation, was that the US would bring pressure to bear on foreign governments to follow its policy by refusing permission to reprocess, either at home or elsewhere, fuel which had previously been enriched in the US. In practice, this meant most of the enriched fuel extant in the West.

This ban could be implemented under the bilateral agreements covering enrichment of the original fuel. Where customers, said Dr Nye, were in special difficulties from lack of storage capacity, and plants might have to be shut down, the US Government would be prepared to consider special dispensation. But licences to re-export the fuel for reprocessing would be granted only in cases of "clear need". There could be no question of a general dispensation of the kind necessary to support the 10-year contracts under negotiation between the Japanese electricity industry and Britain and France.

These statements evoked widespread and sometimes vehement criticism from countries which would be immediately affected, notably those having no indigenous uranium but busy laying foundations for plutonium-fuelled fast breeder reactors to limit their dependence on uranium imports. One specific criticism levelled against the US was that for reasons of domestic expediency it was prepared to renounce one sensitive technology while expanding another, enrichment; and using, moreover, a technology—the gas centrifuge—which only a few years before it had argued would pose a serious threat to the control of proliferation. More generally it was asked what guarantees a nation could have for placing its faith in the US, whose own motives and intentions regarding fast reactors are uncertain.

Developing nations, whatever their nuclear aspirations, indignantly attacked what they saw as a rich nation's attempt to debar them from a valuable technology. The USSR, which has its own uranium reserves and also reprocesses spent fuel for its satellite nations, keeping the plutonium in Russia, has indicated that it will have nothing to do with President Carter's proposals. The policy could only hamper its own well-developed plans for fast reactors.

As with Russia, Britain has longstanding plans for safeguarding the future of its energy supplies once North Sea reserves run out by burning plutonium in fast reactors. Recycled in this way, Britain's existing stockpile of uranium has an energy content exceeding that of proven coal reserves. Britain also has plans to use its knowledge of the difficult technology of reprocessing to develop an international service, under IAEA safeguards, for nations which would prefer not to embark on this technology, at least at this stage. These plans could be severely hampered by US refusal to grant re-export licences for reprocessing to nations whose fuel has been enriched in the US.

Dr David Owen, the UK Foreign Secretary, in the fullest public response yet by any nation, on 10 May pointed out bluntly some of the weaknesses, as Britain sees it, of President Carter's anti-proliferation policy. He emphasised that Britain remained firmly committed to the principles of non-proliferation. But an effective anti-proliferation policy "must go hand-in-hand with a viable energy strategy", he said. He pointed to routes to nuclear explosives which the US policy would apparently leave uncontrolled. And he further implied that President Carter, far from improving relations, has seriously worsened them in this highly sensitive area of international affairs.

Continued proliferation?

A more realistic approach to the problem might be to assume that nuclear weapons will continue to proliferate. Although their attractions to terrorists have probably been greatly exaggerated, the attraction to governments remains undisputed. And governments would find it far easier to assemble the resources required to make credible nuclear explosives. In 1945 only one nation possessed these explosives. Through the McMahon Act the US debarred Britain, a partner in the Manhattan Project, from further participation in the technology. The UK Government, convinced that it needed the technology for broad reasons of national security, promptly embarked on its own nuclear programme. The USSR and France took similar decisions; and later China and India. An impressive 104 nations have signed the NPT, eschewing nuclear explosives; but another 30 have not, among them some with well-developed nuclear plans.

No moratorium on all, still less on parts, of the nuclear technologies by states already possessing nuclear weapons is credible as a way of stopping one of those 30 nations if it is determined, as Britain once was, to acquire the Bomb. It could even encourage it in such a quest. Neither need these nations try to buy large nuclear power stations costing around \$1,000 million as the source of plutonium. As a study specially commissioned by the US Congressional Research Service concluded last year, a small nation with ambitions for nuclear weapons could satisfy them for an investment as small as \$13 million—\$26 million, by building a small gas-cooled, graphite-moderated type of reactor, capable of making about 10 kilogrammes of plutonium a year. The design data for such a 'plutonium furnace' is already freely available in the open literature, and all the materials and components with the single exception of uranium—which is widely distributed across the Earth's surface—can be bought on the open market.

The UK Government estimates that about a dozen nations already have the basic knowledge and access to fissile materials. By 1987 another 20 could have reached this position. In short, it is already too late to prevent other nations from joining the nuclear club if they are determined to do so. A far more persuasive deterrent would be to create an international climate sufficiently hostile to nuclear proliferation to persuade any would-be aspirants that they would lose much more than they could possibly gain by possession of nuclear explosives. So far this has manifestly not been the case. □

Plutonium fuel pins

USA

Feeling the draft

Legislation to control experiments with recombinant DNA is progressing slowly through Congress. Colin Norman reports

THREE months ago, when Congress first began to consider legislation to regulate recombinant DNA experiments in the United States, many scientists were hoping that a straightforward bill, establishing a uniform set of national controls, would swiftly be put together and passed without too much wrangling. Congress has not obliged, however. When the bill finally emerges, it will be a lengthy and complex document, establishing an elaborate mechanism for setting new regulations, ensuring that they are followed, and providing punishment for those caught flouting the rules. Moreover, a good deal of political manoeuvring is still in store before the bill emerges in final form from the Congressional mill.

At least the legislative machinery is beginning to pick up speed, however. Last week, key committees in both the House and the Senate passed their own versions of legislation, paving the way for consideration of the measures by the full House and Senate in the next few weeks. The House subcommittee on Health, headed by Representative Paul G. Rogers, approved a bill running to 46 pages; it will now be considered by the full Commerce Committee and possibly by the Committee on Science and Technology, before being sent to the House floor. It is unlikely that the draft approved by the health subcommittee will be substantially modified at any of those stages, however. In the Senate, the Committee on Human Resources last week approved a 56-page bill drafted by staff members of the Senate Health subcommittee, headed by Senator Edward Kennedy. It will probably be sent to the full Senate next month.

The two versions differ significantly in their approach to regulating recombinant DNA research, and thus a Senate-House conference committee will eventually be given the task of putting together a compromise bill.

Though there are substantial differences in the two bills, there are a number of important points of similarity. Both would require new safety regulations to be established, governing all recombinant DNA experiments in the United States. They also both require that facilities in which recombinant DNA experiments are con-

ducted must be licenced, that violators be subject to heavy fines, that extensive records be kept, and that federal inspectors have a right to investigate facilities and records. They also call for a study of long-term implications of genetic engineering, and they both come close to specifying that the federal regulations should take precedence over controls imposed by state or local governments. The big difference is that the Senate version would establish a Presidentially-appointed regulatory commission to draft and enforce the regulations, while the House version would leave much of the day-to-day enforcement to local biohazards committees.

The House bill, though largely written by committee staff members, was put together during three lengthy committee meetings at which about half-a-dozen Congressmen took an active interest. The chief provisions:

- The Secretary of Health, Education and Welfare (HEW) would be required to draft new regulations governing recombinant DNA research. They would prescribe physical and biological containment conditions for different categories of experiments, set out training requirements for laboratory workers and researchers, specify systems to monitor for the escape of potentially hazardous organisms, require medical surveillance of laboratory personnel, and describe reports and records which must be maintained in research facilities. The regulations would have to be published within one year after the bill is passed, and they would come into effect six months later. In the meantime, the NIH guidelines would be made applicable to all recombinant DNA experiments, no matter whether they are conducted in public or private institutions.

- A part-time advisory committee, consisting of 17 members appointed by the Secretary of HEW, would be established to assist in drafting and implementing the regulations. A majority of the members would be people who are not engaged in recombinant DNA research, and the committee would include a laboratory worker and a representative from industry.

The guts of the bill is a provision establishing a mechanism for licencing facilities housing recombinant DNA experiments. An application for a licence would have to contain a thorough description of proposed experiments, including experimental protocols, assurances that the regulations would be followed, and an analysis of the potential risks to public health or

the environment arising from each proposed experiment. The application and granting procedure would vary according to the type of experiment proposed, but in every case, local biohazards committees would play a strong rôle.

These would be committees consisting of between 9 and 15 members, including at least one laboratory worker and one local public health official. A majority of the committee members would be scientists. The biohazards committee would review all licence applications for facilities under its purview, and it would have the power to grant licences for experiments requiring low containment levels—P1 and P2 under the NIH guidelines. For research requiring P3-level containment, the licence application would have to be reviewed first by a biohazards committee, and subsequently by the Secretary of HEW and his advisory committee. The Secretary would be able to override a negative recommendation by his advisory committee, but in practice such a decision would be unlikely. A similar procedure would be required for applications involving P4-level work, but in such cases the Secretary would be able to grant a licence only if his advisory committee recommended approval.

It should be noted that, by specifying different arrangements for experiments requiring P1, P2, P3 and P4 levels of physical containment, the legislation presumes that such levels will form the basis of the final regulations.

The House bill would leave most of the inspection of facilities and monitoring to the biohazards committees, though federal inspectors would also be empowered to check to ensure that the regulations are followed. Violations could result in revoking a facility's licence, and in addition researchers could be subject to fines amounting to \$5,000 per day for each offence. Particularly serious and wilful violations could result in a \$50,000 fine and up to a year in prison. The bill also provides legal protection for workers who blow the whistle on their employers by bringing incidents of flouting the rules to public attention.

The bill approved by the Senate committee would establish a very different regulatory framework. It would set up an 11-member National Recombinant DNA Safety Regulation Commission to draft regulations, issue licences for facilities and monitor compliance with the regulations. The chairman would be a full-time official, while the other commissioners would be part time; all would be appointed by the President. A majority of the commission members would be non-

biologists.

The commission would be required to issue new regulations within 120 days after the bill is approved; they must be at least as strict as the NIH guidelines. The Senate bill also requires that all facilities housing recombinant DNA experiments must be licenced, and licence applications must specify the proposed experiments, the names of investigators and their qualifications. The Commission would be responsible for granting all licences, but initial review and approval of recombinant DNA projects would be undertaken by local biohazards committees. At least one third of the members of the local committee must be non-biologists, and at least another third would be employees of the facility applying for the licence.

The Senate bill also specifies that federal inspectors would have the right to enter facilities to inspect records and equipment. It also requires extensive record-keeping by researchers. As in the House bill, the Senate version specifies that violations could result in denial of a licence, and violators could be subject to a fine of \$10,000 per day.

Though the two bills would probably not lead to the adoption of radically different regulations, they would lead to different forms of bureaucratic control. In particular, a number of scientists have expressed concern that if a large commission, backed by a full-time staff, is established to review and approve each licence application, there could be considerable bureaucratic delay. One scientist also suggested last week that a Presidential commission to oversee recombinant DNA research would amount to 'overkill'.

One of the most controversial points in the legislation has been the question of whether federal regulations should override controls imposed by state or local governments. In fact, that was the only point which was even discussed during the Senate committee's consideration of the bill last week. The House and Senate versions are not greatly different in their requirements. The Senate bill would allow local governments to set stricter controls only if the extra safety precautions are "material and relevant" to deal with "health and environmental concerns or comparable compelling local conditions", and if they are not "arbitrary or capricious". The House bill would allow stricter local controls only if the Secretary of HEW determines that they are "necessary to protect public health or the environment".

The bills are not likely to reach the floor of either the House or the Senate much before the end of July, and it will then take several weeks for a conference committee to draft a compromise between the two versions. □

● An intensive lobbying campaign by space scientists has won a reprieve for two high priority projects, the Large Space Telescope and the Jupiter Orbiter Probe. A key Senate appropriations subcommittee last week voted funds for both projects, in spite of opposition from Senator William Proxmire, the subcommittee chairman. The vote will almost certainly ensure that the telescope will go ahead as planned, but prospects for the Jupiter project are a little less certain.

The Large Space Telescope seems assured of Congressional support because it has already been approved by the House of Representatives. Last week, the House passed a budget bill for NASA which contains funds to begin building the instrument in the 1978 fiscal year. Thus, if the full Senate follows the recommendation of Proxmire's subcommittee, which is likely, both the House and Senate versions of the NASA budget bill would contain funds for the telescope, thereby virtually guaranteeing final Congressional approval for the project.

The Jupiter Orbiter Probe is still in some trouble, however, because no funds for the project were included in the House bill. The House Appropriations Committee had specifically deleted the money from NASA's budget request, arguing that approval of two major space science projects in one year cannot be justified. The space telescope has higher priority, the committee said, and therefore the Jupiter project should be dropped. The full House followed the committee's recommendation.

It thus seems likely that the Senate version of the NASA budget bill will contain funds for the Jupiter project, the House version will not, and the matter will have to be decided by a House-Senate conference committee. NASA is hoping that it can persuade the conference committee to approve the project.

It is likely that the conference committee will in fact provide some funds for the project, but not as much as the \$20.7 million that NASA requested for 1978. In that case, NASA would at least be able to begin building the spacecraft and it would be able to avoid laying off scientists and engineers at the Jet Propulsion Laboratory, which will manage the project. The spacecraft is scheduled to be launched late in 1981 or early in 1982.

● President Carter's plan to slow down the development of a commercial liquid metal fast breeder reactor is,

like other key elements of his energy policy, being severely mauled on Capitol Hill. Carter had proposed that a demonstration breeder reactor, scheduled to be built on the Clinch River in Tennessee, should be deferred indefinitely, and he recommended that virtually all the funds for the project should be deleted from the budget for the Energy Research and Development Administration. Last week, however, the House Committee on Science and Technology voted by 19 to 11 to approve the Clinch River plant and it restored \$150 million to ERDA's budget to begin constructing the facility next year.

The vote far from guarantees that the Clinch River plant will be saved from the axe, but it does at least ensure that there will be a full-scale debate on the matter when the ERDA bill reaches the House Floor. Senator Howard Baker, who represents Tennessee, reportedly said last week that the vote has made him "optimistic for the first time" that the plant will be reprieved.

Carter's recommendation that the Clinch River plant should be cancelled was a key part of his plan to prevent the use of plutonium as a reactor fuel. He also proposed that the United States should defer indefinitely the reprocessing of spent reactor fuels to recover plutonium for recycle in light water reactors. At the same time, the Administration is trying to dissuade other countries, particularly those which do not possess nuclear weapons, from entering the so-called plutonium economy.

The House Committee on Science and Technology was persuaded, however, that other countries would not defer their plans to recycle plutonium and build breeder reactors. The committee therefore argued that the United States should not allow itself to be deprived of a technology which other industrialised countries are vigorously pursuing.

Similar statements have also been made by Senator Frank Church, who heads a key energy research subcommittee in the Senate, and by Senator Henry Jackson, who chairs the Senate Committee on Energy and Natural Resources. Their support for the breeder programme is almost certain to force a full debate on the Clinch River plant in the Senate.

Thus a protracted debate on Carter's plutonium policy seems assured in both the House and the Senate. At this stage, nobody is willing to predict the outcome.

Colin Norman

EEC

Council flat

The EEC Council of Energy Ministers and Council of Environment Ministers both met in Luxembourg last week. Patricia Kelly and Chris Sherwell report

THE two councils held last week shared a common vein. There were no concrete decisions; and a mass of texts was referred back to national experts for further discussion. Thus it was hardly surprising that one of the most useful discussions demanded no decisions in the first place. That was the debate in the energy council on nuclear energy.

The debate had a status analogous to the open discussion at the March council on energy conservation. The Energy and Research Commissioner, Dr Guido Brunner, worried about negotiations with the US and Canada, wanted the session behind closed doors, but no one agreed. Discussion centred on Community problems relating to uranium supplies, reprocessing and waste management.

More specifically, the idea of Community responsibility for safety aspects of the fuel cycle was discussed. Unsurprisingly, some concern was expressed at the idea of handing over responsibility on a matter where political control could prove so important. The question of Community participation in the high level study set up by the recent London summit was also raised, but not pursued.

On nuclear power forecasts, Britain, together with France and Germany, found the Commission's 1985 projections optimistic. Britain also criticised a suggestion, in a Community paper prepared for the meeting, for a high temperature reactor project—memories of Dragon are still fresh. There was no discussion of the vexed problem of nuclear accounting, over which a controversy, involving past uranium shipments, had blown up since the last council. The matters of nuclear costs, of public opinion and of the fast breeder could only be mentioned.

In restricted session the UK Government refused to accept what it interpreted as an enforced share-out of its North Sea oil with the rest of the Community in the event of a new world energy crisis. It was agreed that in the case of an emergency, EEC headquarters would order a 10% cut in oil consumption for two months. The Commission wanted the percentage of the cut for those countries that cannot easily find substitutes for oil to be calculated in terms of that country's oil

consumption only; in countries where substitutes are more readily found, this percentage would depend on total energy consumption including oil. Italy's Carlo Donat Cattin was anxious that the Italian dependence on oil should be safeguarded in the event of a crisis. But Britain's junior minister, Dr Dickson Mabon, said that as the Community's only major energy producer, the UK was not prepared to cut its consumption more than other countries at the dictation of the Community.

It was clear that while the UK Government would be ready to help those countries most affected by an energy crisis, it could not accept a decision taken by a qualified majority vote in the council. Britain was the only country that did not want the council to depart from unanimous voting. Ministers instead agreed that if a structural problem was affecting any member state, should the Commission order a cut, the council would undertake to meet within ten days of specific proposals from the Commission.

On the matter of the minimum safeguard price for oil there was apparently little effective discussion. But the Dutch minister, Rudi Lubbers, raised the question of long-standing Dutch proposals on energy prices generally. He argued that EEC energy prices should be brought up to oil parity to encourage conservation. But Dr Mabon commented that it was too early for common pricing. The council also disagreed about Commission proposals on how to tackle overcapacity in the Community's oil refining industry. The talks founded on the consultation system where governments would have to seek the Community's approval for new refineries to be built. On top of this, there was no discussion at the council of proposals to regulate financial support for projects exploiting alternative sources of energy.

Three coal texts were among proposals sent back for further discussion. These were the monitoring of imports from third countries, the creation of an EEC financial aid scheme to encourage the burning of coal in new power stations and a system of EEC financial support for coal stocks.

The UK Energy Secretary, Anthony Wedgwood Benn, in the chair for the last time before the new Belgian Minister for Economic Affairs, Willy Claes, takes over the council presidency, said that it had been a solid six months of work during the UK presidency. At Mr Benn's initiative, the council has agreed to hold a general debate at each energy council, on EEC

energy and on world energy.

As for the Environment Council, this seemed doomed from the start. One observer commented that 'red mud', a by-product of the titanium dioxide industry, not only polluted the marine environment but also seemed capable of polluting the atmosphere—notably between ministers. The Italian delegation made it clear that if the council failed to agree with Commission proposals to control waste from the TiO_2 and paper pulp industries—issues on which agreement has long been sought—then it would not agree to a single item on the agenda. The Italians stuck to their guns.

The Nine were split on the old question of uniform emission standards versus quality objectives as a means of control. The British argument, backed up by Ireland and Denmark, is that their industries discharge into tidal waters able to cope with large quantities of pollutants, making the Commission proposals environmentally unnecessary as well as costly to fulfil. France and Italy would like to see all Community countries impose the same controls to avoid putting industries at a competitive disadvantage. Britain maintains that what it gains on environmental cost advantages is lost on transport against more centrally placed Community countries, and was quick to point out that the dual approach to pollution control was accepted by the Nine in 1975 in a directive on the discharge of dangerous substances into the aquatic environment.

Thanks partly to the work of a working group set up during the council, some way of proceeding further may be possible, based on a distinction between reducing pollution caused by waste from an industry and reducing the quantity of the waste.

The council continued in spite of the Italian reserve. Ministers approved a decision establishing a common procedure for the exchange of information on the quality of surface fresh water in the Community. It will be formally adopted when the Italian reserve is lifted. They failed to finish discussion on EEC accession to the Helsinki Convention on protection of the Baltic. Authorisation to open negotiations is expected. Differences between the Dutch and countries through which the Rhine flows before reaching Holland meant no agreement was possible on proposals on the quality of drinking water. The proposals go back to Coreper, the committee of EEC ambassadors, for further discussion. So do proposals on toxic and dangerous waste on which the council did reach a consensus on the main aspects; a directive is expected soon. □

JET

Stalling point

RIDING on the back of a busy day in Brussels last week when the Councils of Energy and Environment Ministers both met (see opposite), the controversial issue of the EEC's Joint European Torus (JET) fusion project blew up again, as it was always destined to do. JET itself has not yet blown up, and for many that is some comfort. But the possibility nevertheless remains, and the absence of a decision on a site for the project, which is and always has been the crucial issue, now symbolically represents all the current problems of cooperation that the EEC would dearly like to avoid.

The background is familiar. Of the original sites proposed for the project, four stood out: the EEC's research establishment at Ispra in Italy; Cadarache in France; Garching in Germany; and Culham in Britain. Italy held out for Ispra until its future was more or less guaranteed through judicious deployment of the EEC's joint research programme for 1977-80. France held out for Cadarache, with CERN as an alternative, until it could do so no longer—which was effectively until it could secure a better deal to present back home. That left Garching and Culham.

The character of that 'deal' is not so familiar. But it was crucial to the failure of the 29 March meeting of the Council of Research Ministers at which the whole matter was to have been finalised. No one talks about deals in the 'open' Community, so even the most popular theories are speculative. But basically the idea seemed to be that Britain would at last have the Community project it wanted by receiving JET, that the project director would be German, and that France's proposed management structure would be used. Agreement would then have been possible on a majority vote.

But something went wrong. The small countries, already apparently miffed at the failure to agree on farm prices earlier that week, objected to the ostensible collusion. The majority shifted and the arrangement, inasmuch as it existed at all, began to fold. Details of the proposed management structure, which apparently involved the creation of a JET board of managers with a degree of detachment from the European Commission, also became an issue, making a decision on the site seem pointless.

At the same time, however, final

approval was somewhat surprisingly given in a separate vote to the joint research programme. Until then the issue was inextricably linked to the matter of the JET site; now the link seemed broken. In fact it wasn't, because there was still the all-important matter of releasing the agreed funds for the programme. This Britain has since refused to do, maintaining that it got its fingers badly burned in March when, in the Energy Council meeting on the same day as the Research Council, its concessions on the Euratom loans scheme unexpectedly failed to yield agreement on a minimum safeguard price for oil. Agreement on that issue had been expected in turn to encourage the intended agreement involving JET and the research programme.

All this left the Community with a need both to finalise details about the management of JET and, as usual, to try to reach an understanding on the site before the next Research Council. Meetings of officials proceeded accordingly. But no meeting of the council was set for before the end of June because it was only then that Britain's chairmanship, by now under suspicion, was due to give way to Belgium's. That spelled trouble, because contracts on which the JET design team at Culham were working were also due to expire at the end of June.

Although the Commission was given the authority in March to extend the project beyond June, and presumably has whatever money it needs to do so (the team's salaries are in fact paid by their own home laboratories), a decision on the future of JET before the end of June could only come in a meeting of the Council of Foreign Ministers which was due this week, on 21 June, or next week, at the heads of government meeting on 29 June. Hence all the activity last week, even though JET was not the business of the Energy Council, nor, strictly speaking, the regular business of the foreign ministers or prime ministers.

The sudden burst was typical of the way the Community conducts its business. Guido Brunner, the Energy and Research Commissioner, on the day before the Energy Council, warned that the absence of a decision before the summer recess—at the Foreign Council or heads of government meeting, in other words—would amount to an abandonment of the

project. He was responding to a telegram received from the JET design team expressing concern over the problem; he had also reportedly received a telegram from Ispra staff complaining about the hold-up in research programme funds which they thought was threatening their jobs.

Then JET came up as a spin-off from the Energy Council when at a press conference afterwards the UK minister Dr Dickson Mabon reminded people of Britain's strong desire to have JET. A parliamentary question in the House of Commons later produced the answer that, although remaining differences had recently been narrowed, if discussion was still in progress by the end of June, "we hope the Commission will again extend the contracts of employment of the design team".

On top of this came allegations in the European Parliament, which were spurned by the UK official there, that Britain's hold-up of research funds amounted to blackmail. The official had admitted publicly that two separate issues were intimately tied together as a political package. But he assured listeners that there was enough money for the research centres to continue work and pay salaries until the autumn.

Then later last week came reports that behind-the-scenes contacts were under way between London, Brussels and Bonn involving third party mediation, perhaps from the next country to hold the chair, Belgium, in an effort to secure a solution before the end of the month.

That must be the fervent hope of all those who want to see the project survive. Yet it remains that the lack of trust Britain has felt over JET since the March débâcle is now almost fully reciprocated by other member states on this as well as other issues. Both sides now want impossible guarantees of a *quid pro quo*, and refuse to move until the other does.

Meanwhile a date for the next Research Council had at the end of last week still to be set. If nothing is achieved by the end of the month, then what is called an "orderly winding-down" of the project will begin. In other words, like the other European project, Dragon, which died last year in such ignominious fashion, JET too could be cancelled for lack of interest.

Chris Sherwell

COMECON

● The recent concern in the West about the dangers of nuclear power evoked a uniform and perhaps predictable response from the Comecon media; such fears, it is alleged, are the result of political scare-mongering and/or capitalist negligence. The nuclear power plants that are designed and built in the Comecon bloc on the basis of Soviet R&D, it is claimed, constitute no hazard to health or the environment.

This confidence, although it may be excellent propaganda, hardly constitutes a sound basis for planning an energy policy which is heavily committed to a change-over to nuclear generation as rapidly as construction and logistical problems permit. (It is estimated that by 1980, some 10% of the generating capacity of the whole Comecon bloc, including Cuba and Mongolia, will be nuclear.)

The risk of accidental pollution, however, is appreciated by the planners. When the Institute of Radioecology and Nuclear Technology was founded two years ago at Kosice, Czechoslovakia, systematic research was begun, not only into the prevention of accidental escapes of radioactivity, but also into the ecology of living organisms in an environment polluted by radioactive waste. According to Milan Zaduba, the Director of the Institute, this is the only research institute in the world making such a study. This unique position, however, will not be maintained for long, since future plans for the institute envisage the gradual transformation of its activity into a programme of multinational cooperation with institutes in the Soviet Union, Poland, and the GDR.

● Bulgaria, as one of the less-developed members of Comecon, has a science and technology programme which is closely coordinated to that of the Soviet Union. At present, there are more than 30 agreements between the two countries involving 17 Bulgarian and 48 Soviet ministries and 20 bilateral working groups. To date, the flow of information has been largely in one direction, the Soviet Union having supplied Bulgaria with two-thirds of her machinery, equipment and complete plants, and with over 6,500 complete sets of technical and scientific documentation.

The flow of information, however, is now becoming somewhat more balanced. Uses are being found for Bulgarian technical documentation and a number of Bulgarian innovations are being introduced into

various branches of Soviet industry. Recently, a joint Soviet-Bulgarian Institute, Interprograma, was founded in Sofia, to develop software for automated control systems for production and management. The name of the institute is reminiscent of numerous Comecon projects and co-

ordinating centres, such as Interkosmos and Interatominstrument, and suggests that the new institute may possibly be expanded, in the future, into a similar multinational body.

The same possibility is also suggested by the recent agreement setting up Intervodochistka, the Comecon international R&D corporation dealing with problems of water conservancy and purification. Under this agreement, Bulgaria is charged with producing the various digital automated units which the corporation will need. From the communique issued by the 80th session of the Comecon Executive Committee in April, it would appear that Bulgaria's responsibility will be extended to providing similar equipment for other branches of the economy.

● Poland's inland waterways have been a matter for concern over a number of years, but it was not until January 1976 that a government decision finally settled the long-standing debate as to whether the waterways were worth modernising and developing at all. By this time, a number of weirs and locks had become urgently in need of repair, but in some cases, the conflicting demands of other sectors (notably the Ministry of Agriculture) have meant that repair work has had to be abandoned. Moreover, during the years of neglect, the waterways had become a convenient means of dumping industrial effluent and sewage, and now only 53% of effluent is treated at all,

the rest being allowed to discharge into rivers and lakes. Some 28% of the total length of the rivers is said to be "beyond economic utilisation".

At present, water consumption in Poland is 13,000 million cubic metres per annum, and is expected to rise to 18,000 million cubic metres in the next few years. While the civil engineers are struggling to produce a rational scheme for the renovation of river installations to cope with modern traffic, plans are also being discussed for the reduction of pollution. Suggested remedies include the use of more easily soluble detergents and pesticides, the recycling of agricultural effluent, and the development of water-saving technologies. One factory, the new Gorazdze cement works in Opole province, however, seems unlikely to add to the pollution problem. Although this plant is sited near the Odra, it needs the river as a means of transport only; the raw materials are prepared by a dry pulverisation process. "The advantages are obvious," commented *Dziennik Ludowy*. "Where there is no water, there is no effluent."

● According to Yu. Maksarev, the Chairman of the State Committee of the Soviet Union on Inventions and Discoveries, one in three of all patent applications in the world is made in the socialist countries. To cope with this vast flow of invention, the Comecon countries are at present engaged on working out a system to improve the national patent information systems of the member countries and also, by means of "division of labour, cooperation, and the centralisation of individual information processes", to increase the volume of information exchanged between member countries.

According to Maksarev, invention in the Comecon member countries is based on a study of world patent information. This study has not, it would seem, had any marked effect on the type of information patented by the Soviet Union, which, with some 100,000 'author's certificates' published in the last three years, is responsible for the majority of Comecon inventiveness. A close study of these 'certificates' reveals that in a significant number of cases, the novelty would be insufficient for a patent to be granted in any Western country, being at best the type of innovation which would be registered as a 'utility', and at worst simply minor modification which, in the West, would be incorporated as an unregistered factory improvement.

Vera Rich

WINDSCALE

Down to business

The Windscale inquiry opened in Whitehaven, Cumbria, last week. Chris Sherwell reports

NO ONE thinks a decision on Windscale is going to be easy; the case is too finely balanced. But practically everyone involved in the inquiry, on the application from British Nuclear Fuels Ltd (BNFL) to develop land there for an oxide fuel reprocessing plant, hopes that the decision will go their way. Once Mr Justice Parker has made his recommendations, probably by the autumn, the responsibility will lie with the Secretary of State for the Environment. Assuming the Labour government survives until then, that will be Mr Peter Shore.

Opening statements from BNFL and from the various opponents of the project were heard last week. Cross-examination of some 18 witnesses to be brought by BNFL also began. The first was Mr Con Allday, the managing director, and he was still on the stand on Friday. Before he appeared the inquiry already looked like broadening the spread of issues it will cover when Mr Justice Parker produced over a dozen points on which he said he and his two assessors wanted early clarification from BNFL.

The points drew attention to figures showing that plutonium recovered through reprocessing would be enough to charge more fast breeder reactors than the country could possibly need. Mr Justice Parker said they wanted to know if one objective was to keep the breeder option open. They also wanted to know how much plutonium was required to fuel a breeder and how much had been recovered and would be recovered from spent Magnox fuel.

The implication was that existing facilities at Windscale for reprocessing oxide fuel—using the 'head-end' plant which is presently inoperative—might cope with domestic reprocessing demands and take some overseas business, and with other work also satisfy Britain's plutonium requirements. In short, was a new plant necessary?

This all fitted with what Mr Justice Parker had said at the start of the whole proceedings about three basic questions needing answers. These were: should spent oxide fuel be reprocessed in Britain at all? If yes, should it be reprocessed at Windscale? If yes, should the plant be larger than that required for domestic purposes in order to reprocess fuel from abroad?

In the context of these questions it

was hardly surprising that the precise terms of the Japanese contract that BNFL has been trying over many months to negotiate also became important soon after Mr Allday took the stand. He was reluctant to furnish the document, yet plainly, without the terms of the proposed contract, no detailed assessment could be made of the financial and economic factors which, for the third question at least, BNFL themselves must regard as relevant. Sight of the terms was subsequently allowed.

Under cross-examination Mr Allday admitted it would be cheaper to use refurbished or rebuilt facilities that existed, but said this would not be enough. He also endeavoured to explain why existing facilities to reprocess spent Magnox fuel from Britain's first generation reactors had failed to operate at full design capacity. He attributed this at least partly to the difficulty of handling spent fuel elements that were in a poor condition because they had stayed in reactors too long. Also broached was the question of what work was being done on dealing with fuel if it should not be reprocessed.

Earlier in the week the inquiry had opened amid a burst of publicity generated by the presence in Whitehaven of nuclear experts, company men, government officials, lawyers, environmentalists, demonstrators and journalists. Many detected a note of resentment among the local people who have to live with Windscale. But the resentment was less at the plant, expansion of which means more jobs, than at the foreign invasion. Non-BNFL voices supporting the project because of the benefits it would bring to the area came from Cumbria County Council and Copeland Borough Council. But another authority, the Isle of Man, is among the objectors, not all of whom agree on the basis from which their arguments can best be launched.

Before the inquiry opened BNFL confirmed that a laboratory at Windscale had been closed following an accident six weeks earlier in which a pressurised glove-box had blown back and released plutonium. During the week, as part of a new policy of directly releasing details of all accidents no matter how trivial, BNFL published a list of incidents that had occurred over the previous two months. These details are usually passed on to the Nuclear Installations Inspectorate and to the Secretary of State for Energy.

The inquiry continued this week with more evidence from Mr Allday. Other BNFL witnesses were also to appear. □

URANIUM

Hot topic

A TEAM of experts from Australia is thought to be in Europe to discuss possible sales of uranium for EEC nuclear power stations. They were expected to visit Brussels to discuss marketing arrangements and review Euratom security controls. The Australian Prime Minister, Mr Malcolm Fraser, visited Brussels last week for talks with the European Commission. He told reporters afterwards that his government had not yet decided on its export policy for uranium. An announcement is expected within weeks now that the second report of the Fox Commission has been published.

In spite of speculation to the contrary, Mr Fraser said that there was no question of a trade-off between possible exports of Australian uranium and greater access to EEC markets for Australian agricultural produce. Overall commercial relations between Australia and the EEC can, however, be expected to influence the matter, and Mr Fraser has attacked the EEC's Common Agricultural Policy.

Mr Fraser would not answer questions about Australia's alleged membership of a world-wide uranium cartel, into which further probings were made in the United States last week when a bundle of internal memoranda of the Gulf Oil Corporation was released by a Congressional subcommittee. They seriously undermine Gulf's contention that it was an unwilling partner in the cartel, and contradict its assertion that the operation of the cartel had no effect on domestic uranium prices in the United States. The memoranda, which were supplemented by a three-and-a-half hour grilling of Gulf's chairman, Jerry McAfee, could pose serious problems for Gulf's defence against possible anti-trust suits.

McAfee persistently claimed at the hearing that Gulf's Canadian mining subsidiary was pushed into the cartel by the Canadian government. He did not give details, however, and some of the internal memoranda depict the company as a willing partner. One memorandum even discussed how the cartel could eliminate competition from other uranium companies. The cartel was formed in 1972, and operated until 1974, a period when uranium prices increased sharply. McAfee and other Gulf officials admitted in their testimony that the increasing world price of uranium had, to a limited extent, also driven up domestic prices in the United States.

The second annual meeting of the Uranium Institute was meanwhile due to take place in London this week. The institute, established in June 1975, exists "to promote discussion between uranium producers and consumers", particularly on uranium supply and demand. It has 36 members, including 21 producers and 9 consumers. There are no US members. The institute's secretary general, Mr Terry Price, was among those called to give evidence before a US judge at the US embassy in London last week in connection with a case brought by Westinghouse Electric Corporation concerning the cartel.

IN BRIEF

Petition to Poles

Three Nobel prize-winners—George Wald (medicine), William Lipscomb (chemistry) and Kenneth Arrow (economics)—and some twelve other well-known American scientists are among the 139 signatories of a petition to the Polish government asking for the immediate release of the imprisoned members of the Workers' Defence Committee "whose only crime consists of defending the basic human rights of others".

Meanwhile it is reported from Moscow that the physicist Professor Mark Azbel has, exactly six years after his first application, been granted permission to emigrate to Israel. Since 1974, when Professor Alexander Voronel went to Israel, Azbel has been chief organiser of the illicit Sunday Seminars for refusenik scientists.

UK joins in on test ban

The Soviet Union and United States began talks in Washington last week on how to achieve a comprehensive nuclear test ban. The Russians are reported to be keen to come to some agreement on a test ban and President Carter is said to have made it a priority in his programme of arms control.

As the result of a Russian request Britain will join the two super powers, starting 13 July, in drawing up a comprehensive nuclear test ban treaty. The three countries have collaborated before on nuclear arms control, in 1963 on the partial test ban treaty and in 1968 on the non-proliferation treaty. It is thought likely that Britain will go along with a comprehensive treaty provided that it includes nuclear explosions for peaceful as well as military purposes.

Neutron source

Rutherford Laboratory has been given the go-ahead to build a spallation neutron source. The announcement, during the official opening of the laboratory's laser facility (see page 666), greatly eases the transition of the Rutherford into a new era.

Nimrod, the laboratory's 7 GeV proton accelerator, is due to close in 1978, and although the new laser facility goes some way towards using the laboratory's expertise, there had been fears that in the absence of further projects there would have to be redundancies. The spallation neutron source, however, in which 800 MeV protons pulsed at 50 cycles per second will be fired at a heavy element source to break up nuclei and yield fast neutrons, will use much of the existing human and hardware investment in Nimrod.

I recently attended the 1977 Sponsored Film Festival, organised by the British Industrial and Scientific Film Association and held in London during ten days in May. During that period 188 films and video tapes were shown, and numbers of prizes were awarded by distinguished panels of judges. The films were divided into ten categories—education, training, safety, technical, scientific and research and so on. I restricted my attendance to "Ecology and the Environment".

This was an interesting, and, to me, a new experience. Although in my youth I was an enthusiastic film goer, witnessing the change from the silent film to the 'talkie', and the peak of the industry's prosperity, I have not been inside a commercial cinema for several years. I occasionally watch old feature films on television, and have often seen, and used, short scientific films at lectures and conferences. I have even been concerned with making some such films. But I have never before sat from 9.30 am to after 5 pm watching a continuous series of moving pictures.

I found that the organisers of the festival had given our theme a wide interpretation, for in addition to seeing productions about energy and pollution, nature reserves and the protection of wildlife, we were also treated to propaganda films trying to persuade us to visit Guernsey, the Lake District or the historic castles of England and Wales.

In one way or another, the oil industry was prominent. The government's Central Office of Information screened "Clean and Pleasant Land" showing the horrors of oil pollution on the sea and the beach, and how

Britain was coping with the problems. Two potential polluters, British Petroleum and Shell UK brightened their tarnished images with an admirable sermon on energy saving and a pic-

Ecology on film**KENNETH MELLANBY**

ture of the, as yet, unspoiled Peak District National Park.

Most of the rest of the programme was more truly environmental and ecological. The Royal Society for the Protection of Birds, Britain's largest voluntary conservation organisation, showed two films made by their own unit. In the first, David Bellamy, one of our leading telly-dons, described the dangers to our small areas of surviving heathland. In the second, Ian Prestt, the Society's Director, spoke persuasively about its work. These combined propaganda with education, and included good and unusual natural history photography.

However, as I watched, I wondered if some films might not, by their very excellence, defeat their own objectives. For instance "The Petersfinger Cuckoos" enabled the cinema audience, and those who watched it on television, to observe the most intimate details of the private life of this elusive and parasitic bird. It all looked so easy, yet we know that "the few seconds of the secretive cuckoo laying its egg took more than 1,000 hours of waiting and watching". I have sometimes been worried lest inexperienced town-dwellers who have watched such programmes may be discouraged when they visit the country and see comparatively little wildlife, even on a nature reserve with the help of a skilled naturalist.

Fortunately, this does not seem to be the case. The sound of the voice of a real, wild, live cuckoo seems to be appreciated all the more. When, at our home in Huntingdonshire, we open our rural and unkempt English garden to the public, to raise money for various worthy conservationist causes, we set out a simple nature trail demonstrating wild flowers ('weeds' to the conventional gardener), birds' nests and even newly-dropped fox dung. We find that most of our visitors, and all of their children, appear to be enthralled. It seems that the most sophisticated nature films are treated as something different from real life, in the same way that violence in Westerns and crime programmes seems unrelated to that experienced in our streets and after football matches. Nature films are undoubtedly useful, but they are no substitute for the real thing.

Unemployed scientists

SIR,—Your article (21 April, page 668) describing the plight of Soviet scientists who have been refused employment and have tried to carry on their work in isolation rang a familiar bell. But, although the world receives news of these unhappy people in the Socialist countries, no mention is made of the plight of hundreds of unemployed biologists, chemists, physicists, and mathematicians in the Free World.

Any science department in Canada which ventures to advertise a vacancy gets snowed under by anywhere from 75–400 applicants most of whom are underemployed and receive no professional recognition from their colleagues. Despite this, universities go on pretending that no such problem exists, and have not taken steps to expand their faculty to alleviate it. The unemployed scientist has no faculty union, cannot apply for research grants, cannot receive travel grants, and must work in isolation. He is barred from receiving unemployment assistance unless willing to seek any type of work, thereby relegating his professional career, for which he and his parents have paid dearly, to the status of a part-time hobby.

Every government adopts certain policies for eliminating its unwanted and superfluous citizens. The methods of the Socialist and Free-World countries differ only in superficial aspects. A doctoral student whom I taught at the University of Calgary sought suitable employment for five and a half years from 1968–73, before taking his life, leaving a widow and three small children. Can we truly say that such people have suffered any less than the 'refusniks' of the Soviet Union?

Yours faithfully,

JAMES J. KLEIN

University of Regina,
Saskatchewan, Canada

Let n be the psammity

SIR,—What is the quantity of which the mole is the SI unit? It is 'amount of substance' (in French *quantité de matière*). However, Newton's definition of mass was as quantity of matter (in Latin *quantitas materiae*), and the word 'substance' carries overtones of theology and mediaeval philosophy. It is only necessary to recall the snickers

among scientists when 'amount of substance' was introduced, or the bewilderment of students who try to make sense of the expression, to realise that 'amount of substance' does not describe what it names, and that English needs a simple word for this quantity, as German has *Stoffmenge*.

Common speech does not have a word that can readily be extended to cover the concept, but several classical roots might yield a suitable word. Although grains of sand had been a Greek metaphor for uncountability, Archimedes in his *Sand-Reckoner* (*Psammités* in Greek) calculated the number of grains of sand that would fill the known universe. To replace 'amount of substance,' I propose 'psammity', evoking Archimedes' calculation and treated as if there were a Latin *psammitia* from which it derives, with combining form 'psammito-' and adjective 'psammitic'.

How would these be used? It is usual to write, "Let m be the mass . . .", and only later need it be revealed that the unit will be the kilogramme. On the other hand, at present we write, "Let n be the number of moles . . .". If instead we write, "Let n be the psammity . . .", the dimension of n is clear, but the unit, whether mole, micromole, or pound-mole, need only be specified when numerical values are given. Again, when the density of a gas is expressed in moles per unit volume we must at present speak of molar density, but this would become psammitic density. Other uses of psammity follow by simple analogy with mass and length, where common usage already distinguishes the quantity from the unit.

Yours faithfully,

GEORGE S. KELL

National Research Council,
Ottawa, Canada

Microprocessor myths

SIR,—I fear that some of the 'myths' mentioned in Basil Zacharov's article on microprocessors (28 April, page 760) were actually fluffy and insubstantial.

It is true that microcomputers cost more than microprocessor chips; more, even, than naked minis. But what is of genuine importance is this. One can now buy—and pay for—only as little computing power as one actually needs, right down to a four function calculator costing \$7. No longer must one

spend the \$7 every half hour in connection charges, and waste time keeping up on the latest system releases, just to be able to calculate small profundities on demand.

Microcomputer users may also spend inordinate amounts of time writing software, but after all, anyone making many small-scale runs, rather than engaging in massive, production number-crunching, must write a seemingly inordinate quantity of software (or spend almost as much time learning to use canned software). The microcomputer also has one overwhelming advantage with respect to the software investment: ownership and control. That control provides a modicum of assurance that one's heavy investment in software will not suddenly be destroyed or devalued at the whim of an outside party. The real question is: how can anyone afford not to use a computer small enough to own, whenever possible?

It is also true that microcomputers are not fast, complicated, and sophisticated like minis and mainframes, but the power of a pocket calculator is sufficient for a large class of tasks. A microcomputer system costing a mere \$1,700 is likely to be severely limited by the user's communication speed.

None of this is new. After all, that 'complex internal organisation' which allows a big mainframe to perform 'many concurrent activities' is customarily installed precisely so that the mainframe can simulate a hundred or a thousand small computers running at once, each serving a different user. Today, we can sometimes spare ourselves that nonsense, and simply purchase the hundred computers.

Small computing tasks have tended to be served inconveniently, expensively, and sometimes even with grudging arrogance, by traditional computer facilities. Microcomputers and LSI technology complete the low end of the continuum of computer powers. It should, therefore, not be hard to understand the microprocessor phenomenon. After all, it is practically one and the same with the calculator revolution. Even diehard advocates of mainframing everything have been known to use calculators.

Yours faithfully,

PAUL SCHICK

New laser facility at Rutherford

from T. P. Hughes

THE Science Research Council's Central Laser Facility at the Rutherford Laboratory was officially inaugurated on 20 June. The occasion marks the successful completion and commissioning of the most powerful pulsed laser in the United Kingdom, whose output is available to University research workers for a variety of experiments.

The original proposal for a central facility came from several University groups investigating aspects of laser-plasma interactions. The experimental groups had previously built their own high-power lasers, but needed even higher powers to extend their work to higher plasma temperatures and densities and laser irradiances. They were acutely aware not only of the high cost of large lasers, but also of the difficulties of maintaining a reliable output from home-made systems, whose servicing occupied a disproportionate amount of time at the expense of the interaction experiments themselves. After extensive discussions, it was decided to ask the SRC to provide and operate a large neodymium laser, and to make funds available to update it and, in due course, to replace it with another laser as techniques develop.

The scientific objectives of the Laser Facility are to create and study dense plasmas generated by the laser compression of matter; to study inter-

actions of intense laser radiation with matter; and to develop new and more efficient high-power lasers for these and other purposes. The creation of very dense plasmas by ablative compression of small isolated targets is currently being investigated in several laboratories throughout the world as a potential route to controlled nuclear fusion, but it has a much wider scientific significance. It is now possible to produce plasmas in the laboratory with temperatures and densities similar to those which are believed to occur in stellar interiors. Information about spectral line shapes and intensities, about radiation and other energy transport processes, and about the equation of state in these plasmas will be of great value to astrophysicists. Several other experiments using the laser facility were also envisaged in the original proposals, including the development of VUV (vacuum ultraviolet) and X-ray lasers, studies of gas breakdown and experiments in quantum electrodynamics.

Experimental programme

At a meeting of prospective users from the Universities and other laboratories in December 1975 the basis of the initial experimental programme was agreed. Detailed proposals were prepared for single-beam experiments to begin when the "driver"

stage of the neodymium laser was ready, with an output of up to 10 J in a 100 ps pulse, and for two-beam experiments using the full laser system to compress glass microballoons. During the following 12 months groups of scientists, each drawn from several universities and other laboratories, collaborated with the staff of the newly-formed Laser Division of the Rutherford Laboratory to design and construct a large target chamber and a wide variety of experimental equipment. In the meantime, the laser was being installed and tested. The first single-beam experiments began in December 1976 and continued until the end of March 1977, with several pauses to permit further work on the laser. During this period many plasma diagnostic techniques were tested and some valuable X-ray and VUV spectroscopic data were recorded, including information relevant to the interpretation of solar flare spectra. Preliminary observations of the time required for the laser pulse to burn through thin foil targets, prepared at the Rutherford Laboratory, were compared with computer calculations to obtain information about the thermal conductivity of the plasma layer. The two-beam laser system was completed in April 1977; the first shot at a microballoon target produced compression, as recorded with an

The illustration shows a space-resolved X-ray spectrogram from laser-compressed neon-filled glass microballoon.

X-ray pinhole camera. In this experiment the glass microballoon, 85 μm in diameter and with walls 0.5 μm thick, received only a tenth of the full rated power of the laser, focused with two $f/1$ lenses. Further experiments using microballoons selected, mounted and filled with gases such as neon and argon at the Rutherford Laboratory are now in progress (see illustration).

The laser pulse is formed initially by switching out a single spike from the mode-locked output of a neodymium-YAG oscillator. Its duration may be varied between 30 and 300 ps. A series of neodymium glass rod amplifiers of increasing diameter, interspersed with Faraday isolators and spatial filters, produces an output pulse from the driver stage with an energy of up to 10 J in a single beam of 76 mm diameter. The beam is then divided into two parts, each of which passes through a further rod amplifier into a 10 cm diameter disk amplifier to give a rated output of 40 J, corresponding to a total output of 0.8 TW in a 100 ps pulse. For stable operation and to prevent damage from dust particles, the laser is housed in an air-conditioned clean room: the beams emerge through ports in a partition into a separate target area. Here beam steering reflectors direct the laser pulses into the main target chamber. This chamber, which is evacuated, has more than 40 ports for windows and for diagnostic equipment. Within it, attached directly to the laboratory floor and isolated from the vacuum envelope by bellows, is a massive optical table on which are mounted the target holder and the two large aspheric focusing lenses. Focusing adjustments are made with the aid of a continuous wave Nd-YAG laser and a TV telemicroscope: the peak irradiance in the focal spot due to a single beam is in the region of 10^{15} – 10^{16} W cm^{-2} . The laser is controlled from another room which also houses recording oscilloscopes and a small computer used to monitor the laser and to acquire and process experimental data.

More than 30 University research workers from eight Universities are at present participating directly in the experimental programme. Theoretical and computational work on related topics, including notably the hydrodynamics of the compression of spherical targets, is also in progress at five Universities. For many of those involved in the experiments, accustomed to working in comparative isolation, collaborative research is a new and stimulating experience, which imposes its own discipline on their

activities in exchange for access to the best available research equipment, and for the rapid progress which is possible when new results and ideas are immediately and freely shared. The Rutherford Laboratory has, of course, been running collaborative research programmes, notably in high energy physics, for many years, and provides excellent facilities for visiting scientists.

The present programme of research will continue well into 1978. More sophisticated focusing optics, providing more uniform illumination of spherical targets, will be supplied shortly. New experiments on X-ray and VUV lasers are currently being planned. The rate of progress is limited by the availability of laser shots, and this situation is likely to persist into the foreseeable future: the Laser Facility is already as heavily loaded as staffing permits. Nevertheless, proposals for appropriate new experiments will always be welcomed. $\square$

Neutron scattering and ribosomes

from Richard Brimacombe

PHYSICAL chemistry has had a difficult time in coming to grips with the ribosome; in the past, all too many painstaking studies have led only to rather unsatisfactory conclusions, usually involving unspecifiable conformational changes or else bemoaning the complexity of intra-ribosomal interactions. This is however by no means the case with neutron scattering measurements, which are beginning to give fairly precise estimates of useful intra-ribosomal distances, the most recent contribution being a paper by P. B. Moore, J. A. Langer, B. P. Schoenborn and D. M. Engelman (*J. molec. Biol.* **112**, 199; 1977), entitled 'Triangulation of proteins in the 30S ribosomal subunit of *E. coli*'.

Neutron scattering has already been applied to the *Escherichia coli* ribosome to measure the distance between the centres of mass of protein and RNA within the ribosomal subunits, and here it appears that in the 30S subunit, centres of mass are more or less coincident (Moore *et al.* *J. molec. Biol.* **91**, 101; 1975). On the other hand, in the 50S subunit they are separated by a significant distance, indicating that the large subunit has a protein-rich and RNA-rich region, although there is some disagreement as to the magnitude of the displacement (Moore *et al.* *Proc. natn. Acad. Sci. U.S.A.* **71**, 172; 1974; Serdyuk & Grenader *FEBS Lett.* **59**, 133; 1975;

Stuhrmann *et al.* *Proc. natn. Acad. Sci. U.S.A.* **73**, 2379; 1976).

Similar neutron scattering studies are currently being made in a number of biochemical systems (for investigating chromatin and virus structure, for example) but the advantage of using neutron scattering to investigate the *E. coli* ribosome is that active ribosomal subunits can be re-assembled from their constituent RNA and proteins, which enables a reconstituted particle to be prepared in which selected pairs of ribosomal proteins are deuterated. The neutron technique not only allows the distance between the centres of mass of the two deuterated proteins to be measured, but also gives some information about the shapes of the proteins concerned. In the most recent paper by Moore *et al.* (*op. cit.*) six such inter-protein distances are described, which, when added to those previously published by the same group (Engelman *et al.* *Proc. natn. Acad. Sci. U.S.A.* **72**, 3888; 1975), gives a total of nine inter-protein distances within the 30S subunit. These are between proteins S2–S5, S3–S4, S3–S5, S3–S7, S3–S8, S4–S7, S4–S8, S5–S6, S5–S8, and the authors are able to use their data to construct a map of the relative locations of the centres of mass of S3, S4, S5, S7 and S8, in which only two distances need still to be measured in order to determine the relative placings of all five of these proteins in three dimensions.

Moore *et al.* conclude that most if not all of the proteins under study have significantly elongated conformations, with protein S7 being particularly oddly shaped. This finding is in full agreement with a number of recent studies, notably small-angle X-ray scattering of isolated proteins (for example Osterberg *et al.* *FEBS Lett.* **73**, 25; 1977), and the mapping of antigenic determinants on the ribosome surface by immune electron microscopy (reviewed by Stöffler & Wittmann in *Protein Synthesis* (eds Weissbach & Pestka) 117–202 (Academic Press, New York, 1977)), which also indicate that many ribosomal proteins are highly extended.

Similar measurements by neutron scattering are also currently being made on the 50S subunit; one inter-protein distance (between L7/L12 and L10) has already been published (Hoppe *et al.* in *Brookhaven Symp.* No. 27, IV 38; 1975), and measurement of several others is in progress. It is clear that the neutron technique has a useful future in ribosome research, and as measurements continue to be made the method will (as Moore *et al.* point out) reveal its own degree of

Richard Brimacombe is in Dr Wittmann's Laboratory at the Max-Planck-Institut für Molekulare Genetik, Berlin-Dahlem.

T. P. Hughes is a Senior Lecturer in the Department of Physics at the University of Essex and a Consultant to the Laser Division of the Rutherford Laboratory.

self-consistency; within the three-dimensional lattice, each new distance serves as a quantitative check on some of those already measured.

The elongated nature of the proteins makes it rather difficult to compare the neutron results in any detail with other data, such as protein-protein cross-linking results, or the immune electron microscopy technique mentioned above. There is however another physical technique which gives data very similar to those obtained by neutron scattering, and this is the measurement of energy transfer between fluorescent dyes (Huang *et al. J. molec. Biol.* **97**, 443; 1975). Here the ribosome is re-assembled with two specific proteins labelled with two different fluorescent dyes, and the energy exchange between them can be measured in the reconstituted particle. Making certain assumptions, this gives an estimate of the relative distance between the centres of mass of the proteins concerned (although without giving any information on shape), but unfortunately the set of protein pairs which have been determined by this latter method does not overlap sufficiently with the set measured by neutron scattering for a direct comparison to be made. It is however obviously only a matter of time before the two sets of data do begin to overlap, and that should be something well worth waiting for. □

Surface antigens specified by the *T/t* locus

from P. L. Stern

THE idea that molecules displayed on the cell surface may allow differential recognition of interacting cells and therefore be a key factor in morphogenesis is an extremely attractive one. An important corollary to this view is that at least some genes which play an essential part in development would be expected to specify components of the cell surface. So recent observations suggesting that early embryonic cell surface antigens are specified by alleles at the *T/t* locus in the mouse have aroused a great deal of interest. Mutants in this locus affect embryonic development, sperm production and function and genetic recombination (see review by Bennett *Cell* **6**, 441; 1975). Many of these *t* mutants are embryonic lethals when homozygous and

seem to affect development at very specific stages.

In 1970 Gluecksohn-Waelsch and Erickson put forward the hypothesis (*Current Topics Devl Biol.* **5**, 281) that *T/t* products may be expressed on the cell surface and that the defects in the mutant embryos were due to malfunctions in cell-cell recognition and morphogenetic movements. Two lines of evidence from serological studies have suggested that the products of the *T/t* locus are indeed expressed at the cell surface although it has not yet proved possible to identify unequivocally any surface component as a product of any *t* allele.

One of the first candidates for a *t* locus gene product was the component bearing the F9 antigen. F9 antigen(s) is detected by an antiserum prepared by multiple immunisations of syngeneic mice with irradiated F9 embryonal carcinoma cells (Artzt *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 2988; 1973). F9 antigen is not expressed by any adult tissues except sperm and testes germ line derivatives but is expressed in normal embryos. The fertilised egg has no detectable F9 antigen expression but expression increases during cleavage up to the morula stage and can be detected until day 10 of embryonic development (Jacob *Immun. Rev.* **33**, 5; 1977).

This antigen, like the *T/t* locus effects, is expressed in embryonic cells and sperm. It therefore became a candidate for the product of an early acting wild-type allele at this locus, namely *t^{w32}* (*t¹²*). If the *t^{w32}* mutation were affecting the expression of F9 antigen, twice as many sperm from heterozygous *t^{w32}/+t^{w32}* animals as for wild type *+t^{w32}/+t^{w32}* should be required to remove a given anti-F9 activity, provided that sperm cells express each allele carried by the animal. This result was obtained by Artzt *et al. (Proc. natn. Acad. Sci. U.S.A.* **71**, 811; 1974) using quantitative absorption of anti-F9 serum; *t^{w1}* and *T* heterozygote sperm exhibited wild-type absorptive capacity. The interpretation that F9 antigen is specified by a wild-type allele at the *t^{w32}* locus is, however, made difficult by the fact that some recessive *t* lethals significantly suppress crossing over for a considerable length of chromosome 17. Hammerberg and Klein (*Nature* **253**, 137; 1975) have shown by typing H-2-associated antigens of mice carrying recessive *t* alleles, that particular *t* factors (within the same complementation group) represent a certain combination of genes in chromosome 17, a *t* haplotype, which has remained genetically interlocked in mouse populations for many generations. In consequence the differential absorptive capacity of the heterozygous sperm from wild type could reflect the activity of genes anywhere within the region of crossover suppression.

If anti-F9 serum detects the *+t^{w32}* gene product then this gene product

might be altered or absent from *t^{w32}/t^{w32}* embryos although not from other *t^{*}/t^{*}* embryos. Kemler *et al. (Proc. natn. Acad. Sci. U.S.A.* **73**, 4080; 1976) examined the progeny of crosses producing a proportion of embryos homozygous for *t^{w32}*, *t^{w5}*, *t^{w18}* and *T*. In crosses producing *t^{w18}* or *T* homozygotes, anti-F9 serum labelled nearly all the embryos similarly to normal morulae. Among the progeny of crosses producing *t^{w32}/t^{w32}* embryos, a significant proportion were not labelled. Further, the embryos lacking F9 were blocked in their development at the morula stage at which *t^{w32}* arrests development. However when the progeny of a balanced lethal cross producing *t^{w5}* homozygotes were examined, a significant proportion also failed to label with anti-F9 serum. *t^{w5}* is a lethal acting at 6 days of development and belongs to a different complementation group from *t^{w32}*. As pointed out by Kemler *et al.*, since F9 is not expressed by two different *t* haplotypes it cannot at this time be considered the product of any particular wild-type allele of *t*. However it is clear that F9 expression is affected by a region belonging to or closely linked to the *T/t* locus.

The other major approach to serological aspects of the *T* locus has been the production of antisera against *+t^{*}* sperm and absorption with wild-type sperm to remove sperm autoantibodies. *T/t* locus mutations specify serologically detectable antigens on sperm, codominantly expressed, they are not present on other adult cells so far tested (Artzt & Bennett *Nature* **256**, 545; 1975; Yanagisawa *et al. Immunogenetics* **1**, 57; 1974). Serological analysis is difficult because the antisera are generally weak in cytotoxic reactions with sperm. Cross absorptions of anti-*t^{*}* sera with different *t* haplotype sperm have shown that these antisera detect multiple specificities, some of which may be unique for a given *t* haplotype. However it cannot be excluded that anti-*t^{*}* sera detect, in addition to a genuine *t^{*}* antigen, some other unknown antigen specified by a gene linked to *T/t*.

The experiments of Kemler *et al.* have shown that the *t* antigens defined on sperm are indeed expressed on embryos carrying the appropriate *t* haplotype. A sizeable fraction of embryos from crosses yielding *+t^{*}* heterozygotes are labelled by antisera against *t^{w32}*, *t^{w5}*, *t⁰* and *t^{w18}* haplotypes. The important point is that each of these *t* haplotype associated antigens is expressed at the morula stage. Thus it seems that although there seem to be *t*-stage specific lesions in development, there is no temporal correlation in the expression of the *t^{*}* antigens. There is, presumably no sequential switching on of genes coding for surface products which carry these antigens and which have been hypothesised to control important developmental events.

The evidence for the developmental

stage specificity of the *t* lethals has been largely derived from morphological studies of developing homozygous embryos *in utero*. The general interpretation has been that the *t* alleles affect specific cell types within the embryo. Recent work by Wudl and Sherman (*Cell* 9, 523; 1976) has suggested that some *t* mutations are general cell lethals and do not affect a single cell type. When individual *t^{ws}/t^{ws}* embryos are cultivated *in vitro*, all the different cellular derivatives die; control explants of normal embryos survive favourably in these conditions. Wudl and Sherman also claim that the *r^s* mutation may be a simple cell lethal, although Erickson and Pedersen (*J. exp. Zool.* 193, 377; 1975) have obtained different results. Later acting *t¹⁸* mutations exhibit more specific cell lethality since homozygous embryos will develop in ectopic sites, are histologically anaplastic, but devoid of mesodermal derivatives (Artzt & Bennett *J. natn. Cancer Inst.* 48, 141; 1972). Thus it is possible that there are two classes of *t* mutations, those which are lethal for all embryonic cell types and those which have cells that can escape the homozygous condition.

Whether or not the molecules carrying the *t* antigens are involved in cellular interactions in development remains an open question. The complexity of the cellular specificity of *t* mutations, the *T/t* locus genetics and the antisera make the task of answering it difficult. The isolation in culture of cell lines carrying particular *t* haplotypes will avoid the problems associated with sperm cytotoxicity and eventually allow biochemical characterisation of these antigens as with the F9 (Jacob *Immun. Rev.* 33, 3; 1977). The identification of another antigen, PCC4, expressed by multipotent embryonal carcinoma and spermatozoa, but only on the inner cell mass of the newly implanted blastocyst (Gachelin *et al. Devl Biol.* 57, 199; 1977) lends support to the view that surface changes are co-incident with important determinative events in the embryos. □

Food lost to pests

from Robert M. May

FOR crops of grain in mediaeval times, a rough rule of thumb said that of every three grains, one was lost to pests or in storage, one was for next year's seed, leaving one to eat. The yield from modern crops is much greater, and the fraction to be set aside for seed is negligible, but the fraction lost has changed surprisingly little.

Drawing together information compiled by the US Department of Agriculture, Pimentel (*Bull. Ent. Soc. Am.*

Migration of a spreading axis

from Peter J. Smith

THAT part of the East Pacific rise which separates the Pacific plate to the west from the Nazca plate to the east between 0°S and 34°S is the most rapidly spreading section of the world oceanic ridge system. Some of it is also among the most complicated insofar as there may be two very small crustal plates lying between 22°S and 26°S and between 32°S and the triple junction at 34°S, respectively (Herron *Nature phys. Sci.* 240, 35; 1972). Elsewhere, however, the spreading régime appears to be fairly simple, not least in the area around 31°S which has recently been investigated by Rea (*Earth planet. Sci. Lett.* 34, 78; 1977). Here the topographic axis of the rise is now continuous and almost linear. But as Rea has discovered, it has not always been so.

Evidence for past deviations comes chiefly from the magnetic anomalies in the region. The axial anomaly is straight as is that associated with the Matuyama-Gauss reversal at 2.41 Myr. But the anomalies associated with the Olduvai event at 1.73 Myr and the Brunhes-Matuyama reversal at 0.7 Myr are curved. Moreover, in the southern part of the survey area the Jaramillo event anomaly at 0.92 Myr is offset about 10 km right laterally. Thus although the spreading régime may be simple now and may have been simple more than 2 Myr or so ago, things were evidently more complicated between times.

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

Rea interprets these data in terms of local migrations of the spreading axis, following Blakely (*Geology* 3, 35; 1975) who invoked a similar phenomenon to explain spreading rate variations in the northeast Pacific. The axis of the East Pacific rise at 31°S was straight about 2.41 Myr ago but then gradually became more and more concave to the east until it broke in such a way that the southern section was offset to the west compared with the northern section. The break soon healed, however, leaving a continuous, but curved, axis which gradually became straight again. Throughout much of this period the spreading was also asymmetric (greater towards the east) and the total spreading rate varied.

The details of these axial migrations are, of course, specific to the area under investigation; but the underlying processes are more general. It appears to be significant, for example, that when the axial offset occurred, the result was not to move the axis further in the direction of curvature but to return it to a more central position, presumably closer to the underlying magma source. In fast spreading areas the relatively thin lithosphere cannot confine the spreading centre as easily as can the much thicker lithosphere in slow spreading regions, and so the axis tends to waver. When the axial curvature becomes too severe, however, it is relieved by offsetting which reduces the geographical deviation between the ridge axis above and the magma source below.

22, 20; 1976) has shown that in the US in 1974 the losses in agriculture to insects were 13%, to diseases 12%, and to weeds 8%. This sums to 33% of the annual crop lost to pests, broadly defined. Corresponding average annual losses to pests throughout the decade 1951–1960 were 13% to insects, 12% to diseases, and 9% to weeds, and throughout the decade 1942–1951, 7% to insects, 11% to diseases, and 14% to weeds: over this span of time, losses to insects and plant diseases increased, while losses from weeds decreased.

Although the overall fraction of US crops lost to insects has increased despite the application of insecticides, important reductions of insect losses have been made on some crops. Thus

Robert M. May is the Class of 1877 Professor of Zoology in the University of Princeton.

the fraction of the potato yield lost to insects has declined from around 22% in 1910–1935 to 16% in 1942–1951 and 14% in 1951–1960. In contrast, losses in the apple crop (mainly due to codlin moth and apple maggot) in the same time intervals have been 10%, 12% and 13%; this reflects both decline in cultural controls formerly practised in orchards and increased emphasis on cosmetic aspects of marketing. For corn, a major grain crop, insect losses increased from around 4% in 1942–1951 to 12% in 1951–1960: contributing factors appear to be the continuous cultivation of corn on the same land year after year (increasing susceptibility to rootworm), and the planting of corn types that are less resistant to insect depredations. In all, about 1.2 billion pounds of pesticides (insecticides, herbicides, fungicides), or about 6 pounds per person, are at present

used annually in the US. These pesticides are not distributed uniformly among all crops; the non-food crops of cotton and tobacco for example, account for 50% of all insecticides used in agriculture.

Of particular interest are the patterns of control with pesticides compared with the broad range of bioenvironmental controls, which include cultural manipulations (such as crop rotation), natural enemies, and genetic resistance. Pimentel's survey of the USDA data shows that for insect pests, bioenvironmental controls are used on about twice as many acres as insecticidal methods (9% compared with 5%). For plant pathogens, some form of bioenvironmental control is used on 90% of acreages compared with only 0.5% on which fungicides are used. Crop rotations have been, and continue to be, a major control method for many crop diseases; the absence of a crop for a year or so can cause the population of its pathogens in the soil to die out. For weeds, the estimate is that bioenvironmentally controlled acreage beats that treated with herbicides by 80% to 15%. The relation between the life-history strategy of a pest and the best way to control it is a fascinating one, and the subject of much contemporary research (see *Nature* 264, 211; 1976).

In the US, crop losses from birds and mammals are small (estimated around 1%), although they can be significant for particular crops, such as cherries. Post-harvest losses are, however, substantial. Such losses of stored food to insects, rodents, and microorganisms are estimated around 9%. Adding pre- and post-harvest losses, we see that in the US a total of about 39% (33% plus 6%) of the total food supply is lost to pests.

For the world as a whole, crop losses to pests have been estimated to be about 35% (Cramer, in a journal deserving full citation, *Pflanzenschutz-nachrichten* 20, 1; 1967). This includes destruction by insects, pathogens, weeds, mammals, and birds. The latter two categories of loss are more severe in the tropics and sub-tropics than in temperate regions, but the first three categories remain predominant. Pimentel observes that available evidence tends to suggest that the "green revolution" technology has intensified losses due to pests; recent strains that have been bred with more attention to natural resistance to insects and pathogens may help reverse this trend. Annual world use of pesticides runs around 4.1 billion pounds, or 1 lb per person, with 34% of the total accounted for by North America, 45% by Western and Eastern Europe, and 21% by the rest of the world.

A rough estimate of world post-harvest losses is 20% (Pimentel *et al. Science* 190, 754; 1975), ranging from 9% in the US to 40% and 50% in some of the developing nations in the tropics. Adding these to the pre-harvest losses, an estimate of 48% (35% plus 13%) is obtained for the total food loss. While it may be argued that some of these estimates are a bit on the high side, the fact remains that pest populations (broadly defined) are consuming or destroying something like one-third to one-half of the world's food supply. This is a loss we can afford less and less as time goes on. □

The Earth's core

from C. Hazard

A RECENT paper in *The Moon* (16, 41; 1976) by R. A. Lyttleton must be of considerable interest to geophysicists. The hypothesis that the Earth's core consists mainly of molten iron that drained to the centre quite early on in the Earth's history is so familiar that few seem ever to question its validity. That the core is liquid is demonstrated by the absence of shear waves in it, and that it is metallic is suggested by the requirement of a conducting medium for the electric currents proposed to account for the magnetic field. That the material is iron was conjectured largely on the belief that iron is the only heavy element sufficiently abundant to explain the high density in the core, and implicit in this is the assumption that the core-mantle boundary represents an abrupt change in chemical composition.

However, there is the less well popularised alternative hypothesis that the Earth is fairly undifferentiated throughout and that in fact the core-mantle discontinuity is a change in phase from a non-metallic solid state to a denser metallic liquid state maintained by the great pressure and high temperature within the core. That is, it is a second kind of phase change involving a much greater density increase than the recognised so-called 20°-discontinuity, which occurs at a depth of 413 km where the change is to a different crystalline form.

When the widely held belief was that the Earth in its early stages was molten throughout, the iron core hypothesis seemed to follow as a natural consequence of the heaviest components settling to the centre, but now that cosmogony points to an origin as

a cold body accreting from planetesimals in the original gas-dust solar nebula the phase-change hypothesis has obvious attractions. However, since the late 1940s when proposed by Ramsey (see *Mon. Not. R. Astr. Soc.* 110, 325; 1950), it has found little favour with geophysicists and geologists, although to the best of my recollection it used to be discussed favourably by P. M. S. Blackett in his undergraduate lectures at Manchester in the early 1950s. In recent years the hypothesis has been revived, and its consequences worked out in great detail by R. A. Lyttleton.

According to Lyttleton's development (*Proc. R. Soc.* A275, 1; 1963; *Proc. R. Soc.* A287, 471; 1965) of Ramsey's hypothesis, the Earth formed at sufficiently low temperature to be solid throughout. Then radioactive heating gradually raised the temperature of the central regions to a critical value (of a few thousand degrees K), at which time the catastrophic collapse in a matter of minutes demonstrated mathematically by Ramsey's theory resulted in the sudden formation of a large metallic liquid core. From known seismic data, this core has been shown by Lyttleton to have had a radius just over 2,000 km. Under the influence of continuing radioactivity it has grown steadily to its present radius of 3,473 km, with an accompanying decrease in the overall radius of the Earth of slightly more than 0.1 mm per year, enough to diminish the overall radius by nearly 400 km in 4.5 eons!

It is known that hydrogen just about doubles its density and goes over to a metallic form when subjected to a pressure only about half that at the core-mantle boundary but there is no direct evidence that terrestrial material could also undergo such a transformation. However, in his recent paper in *The Moon*, Lyttleton has produced a persuasive argument in support of the phase-change theory by showing that the contraction required on this hypothesis can quite naturally remove the well-known inconsistency in the tidal theory of the evolution of the lunar orbit, first encountered by Jeffreys in the 1920s and which has remained unresolved ever since (Jeffreys *Mon. Not. R. Astr. Soc.* 80, 309; 1920; *The Earth* edns 2-6, Cambridge University Press, 1920). Jeffreys endeavoured to account for the apparent secular accelerations of the Moon and Sun solely in terms of the lunar and solar couples resulting from tidal friction, but found that the actual observed ratio, 2.9, of these accelerations was far lower than the tidal-theory value of about 7.0. It is this discrepancy that Lyttleton now shows can be removed by introducing terms making allowance for a secularly decreasing moment of inertia of the

C. Hazard is a member of staff at the Institute of Astronomy, University of Cambridge.

Earth, and that the required rate of increase is in remarkable agreement with the previously calculated rate of decrease of the Earth's radius (*Proc. R. Soc. op cit.*; 1965).

Small as the rate of decrease may seem, it yet gives a change in the Earth's angular velocity comparable to that produced by the tidal couples, but of opposite sign and therefore accelerative as required. Lyttleton shows that while a similar but much smaller acceleration could also be produced by separation of iron into the core, such draining down is generally regarded as having occurred largely, if not entirely, early in the Earth's history, and even under the most favourable assumptions as to the present rate, it could not nearly account for the observed discrepancy. It would seem that unless the adherents of the iron core hypothesis can produce a comparably satisfactory alternative explanation for this discrepancy emerging from the standard Jeffreys tidal theory, Lyttleton has struck a telling blow for the phase-change hypothesis for the nature of the core. □

Beaded bubbles

from Robert W. Cahn

AN infinite monocrystalline element containing a second element in solid solution, not liable to any phase transformation, tends to a spatially uniform distribution of the dissolved element, and diffusion will persist until that stable terminal state is attained. That cautious opening sentence incorporates several provisos: if the solid consists of distinct crystal grains or, being less than infinite, is bounded by free surfaces, complications ensue. In general, solutes tend to segregate either to or away from free surfaces or grain boundaries; improved methods of microanalysis have allowed a considerable body of experimental information to be assembled concerning this process of 'Gibbsian' segregation (J. H. Westbrook, in *Interfaces Conference, Melbourne 1969* (ed. Gifkins, R. C., 283 (Butterworth, 1969); E. D. Hondros, *ibid.*, page 77). Hondros's extensive experimental work has led him to the conclusion that solutes with a small equilibrium bulk solubility (usually associated with very different solvent and solute atomic sizes) are particularly apt to segregate to interfaces and surfaces, thereby relieving lattice strain in the solvent. As Westbrook points out,

surface segregation is not restricted to external surfaces; it can apply equally to internal pores, such as are found in imperfectly sintered powder compacts. Westbrook emphasises the role of the binding energy that holds vacancies and solute atoms together; if this is high, any excess vacancies diffusing to a pore must drag solute atoms along with them.

Materials scientists responsible for the design of nuclear fuel elements are currently much concerned with pores—'voids' is the preferred term—in neutron-irradiated metals and ceramics. During irradiation (especially of the metal used to encapsulate the fuel) interstitial atoms and vacancies are formed in equal numbers and diffuse away to 'sinks', predominantly dislocations and grain boundaries. These sinks attract interstitial atoms more effectively than vacancies and the surplus vacancies then assemble to form small voids, visible in the electron microscope. The voids cause swelling of the material, a disease which must be kept within strict bounds for safety reasons. The principal strategy for minimising swelling is to choose suitable base metals and to maximise the concentration of effective sinks for interstitials and vacancies alike. Now, another strategy has been identified.

Some years ago, P. R. Okamoto and H. Wiedersich of the Argonne National Laboratory (*J. nucl. Mater.* **53**, 336; 1974) observed indications that solute elements segregate to radiation-induced voids in a stainless steel. The evidence was indirect—micrographic features indicating pronounced lattice distortion alleged to accompany the segregation—and it was not possible to identify the segregating species. The investigators suggested that it was interstitial solute atoms generated by the irradiation which segregate and lead to the high lattice distortion observed in the electron microscope. Thus Hondros's view that segregation acts to reduce lattice strains is not always in accord with observation.

The whole matter has now been clarified by an elegant set of experiments published by K. Farrell, J. Bentley and D. N. Braski of Oak Ridge National Laboratory (*Scripta Met.* **11**, 243; 1977). They irradiated aluminium foils to very high neutron doses, enough to generate about 0.4 atomic % silicon by $^{27}\text{Al} \rightarrow (\text{n}, \gamma) \rightarrow ^{28}\text{Al} \rightarrow ^{28}\text{Si} + \text{e}$. When the foils were thinned and examined by scanning transmission electron microscopy (STEM), they were seen to contain not only ordinary voids and silicon precipitates, as expected, but also some anomalous voids sitting on the surface of the foil or extending beyond the foil edge. In fact, these voids, bounded by a dark margin, were inhabiting empty space. Very

detailed electron microprobe experiments using the ultrafine STEM beam proved that these free-standing voids were coated with shells (4–11 nm thick) of (possibly amorphous) silicon. The aluminium surrounding them had been dissolved away during the thinning process, leaving hollow silicon spheres standing clear of the foils. Silicon has a small solubility in aluminium, and meets Hondros's criterion for ready Gibbsian segregation.

Farrell, Bentley and Braski point out that this substantial Gibbsian segregation offers the hope of influencing the growth rate of voids, especially in their early stages. The segregated solute must alter the specific surface energy at the void walls and thus affect the efficacy of the void in attracting vacancies—and hence must alter the swelling rate too. If Okamoto and Wiedersich are right in presuming that radiogenic interstitial solutes are peculiarly prone to Gibbsian segregation, then it may be possible to design alloys with initial solutes which, after radiation-induced transmutation, segregate to the incipient voids and inhibit their further growth. That would be an elegant way of setting one consequence of irradiation to neutralise another. □

The plasmopause revisited

from Michael J. Rycroft

WITHIN the charged particle environment of the Earth, which encompasses the ionosphere and magnetosphere, the plasmopause is a physically significant boundary. The plasmopause marks the boundary between the cool, relatively dense plasma of terrestrial origin and the hot, tenuous plasma of both terrestrial and solar wind origin which resides in the outer magnetosphere. This demarcation feature is aligned along lines of force of the Earth's magnetic field; the feet of these field lines touch the Earth's surface at near 60° magnetic latitude. They extend out into space, crossing the equatorial plane at a geocentric radial distance of ~4 Earth radii. Such field lines are termed $L \sim 4$ field lines, using the parameter L introduced by McIlwain as a co-ordinate to order observations of the van Allen radiation belt electrons.

The existence of the plasmopause was discovered independently by two different scientists almost 20 years ago.

Michael J. Rycroft is a Lecturer in the Department of Physics at the University of Southampton and an Adjunct Professor in the Department of Physics at the University of Houston.

Using observations made at Seattle and Stanford, D. L. Carpenter, of Stanford University, California, was studying whistlers. Audio-frequency electromagnetic radiation from lightning discharges, which penetrates the lower ionosphere and is guided from one hemisphere to the other by ducts of enhanced plasma density, which are themselves field-aligned, suffers dispersion. The characteristic signature of the whistler in the frequency-time domain is thus explained. As in much of geophysics, the received signal is the result of integration of a weighted varying physical parameter over the propagation path, and has to be interpreted either by comparison with model computations or by inversion. Using the former method with multipath whistlers, Carpenter showed that the plasma density profile in the equatorial plane decreases smoothly out to $L \sim 4$. There the profile often exhibits a 'knee'; the plasma density decreases sharply, within a fraction of an Earth radius, by an order of magnitude or more, to only $\sim 10^7 \text{ m}^{-3}$. (Carpenter's knee is now termed the plasmopause). He also showed that the plasmopause persisted for several hours at least, and that its L -value was a maximum at dusk, at the bulge in the plasmopause.

K. I. Gringauz, of the Space Research Institute of the USSR Academy of Sciences, Moscow, was studying measurements made by "charged particle traps" carried on the Luna (Lunik) 1 and 2 rockets launched to the Moon. These can be interpreted to yield positive ion density values at intervals along the spacecraft trajectory. With coworkers, he found that the plasma density could suddenly decrease markedly on the outgoing part of the trajectory.

Thus these *in situ* observations confirm the 'remote sensing' whistler observations. The results obtained by one technique complement those obtained by the other. The power of one method (low cost and good temporal coverage for example) is offset by the serendipity of whistler occurrence and their time-consuming analysis. The power of the other method (unambiguous measurement at a point in space) is offset by the high cost of satellite experiments and the fact that many hours—or even days—pass between successive observations at neighbouring points on a particular L -value. In the intervening time, the plasma density may have changed—by an order of magnitude—due to dynamical processes.

A symposium on the Physics of the Plasmopause was held in Trieste in September 1974, under the aegis of the European Geophysical Society. In a special issue of the journal *Annales de*

invited review and contributed papers were published. The subjects covered ranged from peculiar features of the mid-latitude ionosphere associated with the plasmopause to energetic charged particle phenomena, and included treatments of geomagnetic pulsations observed at $L \sim 4$ and of some relevant theoretical problems.

The variations of the L -value of the plasmopause with changing geomagnetic activity (which follows changes of parameters of the solar wind) and at different local times have been investigated by several authors. Most recently N. C. Maynard and J. M. Grebowsky, of the NASA Goddard Space Flight Center, Maryland, have performed such a study based on observations taken aboard the Explorer 45 (or S³-A) satellite. It is curious and, in retrospect, unfortunate that this satellite did not carry an instrument to measure the plasma density directly. However, an instrument to measure the d.c. electric field responds, at low plasma densities, to potentials associated with the Debye sheath around the satellite. As the satellite moves in its 7 h 49 min orbit outwards in the equatorial plane, towards its apogee at a geocentric distance of 5.24 Earth radii, it crosses the plasmopause; there the instrument becomes saturated due to these sheath potentials. Using coincident ground-based whistler and Explorer 45 observations, M. G. Morgan and Maynard (*J. geophys. Res.* **81**, 3992; 1976) showed that saturation occurred at a plasma density of $6 \times 10^7 \text{ m}^{-3}$, to within a factor of two.

In a recent paper, 'The plasmopause revisited' (*J. geophys. Res.* **82**, 1591; 1977), Maynard and Grebowsky have studied statistically the plasmopause position. They have used observations taken over 15 months and covering 1972 completely. The local time coverage was from 2300 LT, through noon to 0800 LT. They found that the plasmopause bulge occurs at 2000 or 2100 LT at geomagnetically quiet times, but migrates towards 1800 LT as magnetic activity increases. During quiet periods, a secondary bulge near local noon is found, confirming results obtained recently by K. I. Gringauz and V. V. Bezrukikh.

Observations of the variation of the plasmopause position with both local time and geomagnetic activity have been interpreted in recent years in terms of the electric field within the magnetosphere. This results from the superposition of the electric field representing the corotation of the inner magnetospheric plasma with the Earth, 'tied' by the geomagnetic field lines, and the electric field resulting from the flow of the solar wind past the magnetosphere which drives the convection

from the night-side to the day-side in the equatorial plane. This latter field may be at least partially 'shielded' from the day-side of the Earth, for example by the shorting-out action of the highly conducting, sunlit ionosphere or by the build-up of space charge layers. The fact that the bulge moves towards dusk, with increasing magnetic activity, indicates that this shielding becomes less effective for the larger convection electric fields occurring then. The secondary bulge in the plasmopause near noon can be explained by the projection of the Sq dynamo electric field, in the ionosphere, along geomagnetic field lines into the magnetosphere.

Maynard and Grebowsky note that the plasmopause L -value is rather better ordered when plotted against Dst , the index of ring current intensity, than when plotted against K_p , the three-hourly, global (planetary) index of geomagnetic activity. This may be explained either by the plasmopause controlling the loss of ring current ions, by way of an ion-cyclotron resonance (loss-cone) instability, or by both the plasmopause and the energetic ring current ions responding together to changes of the convection electric field.

For the future, work remains to be done in the realm of plasma physics, to improve our understanding of the behaviour of the plasmopause as a boundary layer between cool and hot plasmas. The importance of the plasmopause in controlling wave-particle interactions, between whistlers and energetic electrons for example, or between ion-cyclotron waves and multifarious ions, is becoming recognised more and more. Now is the era when we can test the hypotheses that we have developed for the Earth's magnetosphere by applying them to exciting new observations of planetary magnetospheres. Whether or not we have to make reappraisals will remain to be seen. □

A hundred years ago

ON FRIDAY night a series of interesting experiments with the Jablochhoff electric light took place at the West India Docks, under the direction of M. Denayrouze. The apparatus used for the occasion consisted merely of an electro-magnetic machine worked by a small steam-engine, some insulated wires, and the electric candles, which are the invention of M. Jablochhoff, and composed, as we have already described, of two carbons placed side by side with a slip of insulating substance between them, which burns away with the carbon exactly in the same way as the wax of a wax candle is consumed with the wick.

review article

The 'universal' dielectric response

A. K. Jonscher*

A review of dielectric data for a wide range of solids proves the existence of a remarkable 'universality' of frequency and time responses which is essentially incompatible with the multiplicity of currently accepted detailed interpretations. Certain unique features of the universal behaviour strongly suggest the dominant role of many-body interactions.

THE dielectric response of solids has been the subject of extensive investigations for the best part of a century. Existing data cover an enormous range of frequencies from 10^{-6} to 10^{16} Hz, neither limit being absolute. When it comes to theoretical interpretations, the properties of gases and liquids at microwave to optical frequencies are the subject of powerful modern approaches, while the technologically most important response of solids at sub-GHz frequencies remains the subject of piecemeal approaches tailored to individual materials and often based on highly arbitrary models and analytical techniques. In this paper I propose to review some of the available experimental evidence on the frequency, time and temperature dependence of the dielectric parameters for a wide range of solids and to establish the existence of a very general or 'universal' pattern of behaviour which should provide a framework for the classification of a wide range of dielectric phenomena. I will then try to demonstrate the inadequacy of the existing theoretical treatments and I shall propose a novel approach based on many-body interactions. I shall be concerned exclusively with the frequency range below 1 GHz where phonon and quantum phenomena are negligible.

Definitions

A vacuum capacitor with an electric field E between its metallic plates has an interfacial charge $Q_0 = \epsilon_0 E$, where $\epsilon_0 = 10^7/4\pi c^2 = 8.845 \times 10^{-12}$ F/m is the dielectric permittivity of free space and c is the speed of light. If the field varies with time, the charge Q_0 follows exactly, there is no 'inertia' in the vacuum response. If the capacitor is filled with a material medium—gaseous, liquid or solid—the induced charge is increased by the polarisation P of the medium

$$Q = Q_0 + P = \epsilon_0(1 + \chi)E = \epsilon E \quad (1)$$

where ϵ is the dielectric permittivity and χ the susceptibility of the medium.

Since no material medium can follow instantaneously the variations of the field, there is a delay between the polarisation and the field. It is convenient to define the time response to a step-function field, $E(t) = 0$ for $t < 0$, $E(t) = E_0$ for $t > 0$, of the current

$$i(t) = dP/dt = \epsilon_0 E_0 f(t) \quad (2)$$

where $f(t)$ is the dielectric response function. The 'vacuum response' is represented as a δ -function at $t = 0$, but it cannot be resolved experimentally. The response of polarisation to an arbitrarily time-varying signal $E(t)$ is given by the convolution integral

$$P(t) = \epsilon_0 \int_0^\infty f(\tau) E(t-\tau) d\tau \quad (3)$$

which indicates that the system retains 'memory' of past excitations. In a harmonically varying field with radian frequency $\omega = 2\pi f$, f being the circular frequency in Hz, Fourier transformation of equation (3) gives the frequency dependence of polarisation

$$P(\omega) = \epsilon_0 \chi(\omega) E(\omega) \quad (4)$$

where $P(\omega)$ and $E(\omega)$ are Fourier components of $P(t)$ and $E(t)$, respectively, and $\chi(\omega)$ is the complex Fourier transform of $f(t)$

$$\chi(\omega) = \chi'(\omega) - i\chi''(\omega) = \int_0^\infty f(t) \exp(i\omega t) dt \quad (5)$$

where $i = (-1)^{1/2}$. The real component χ' gives the component of polarisation in phase with the field, the imaginary component, known as the dielectric loss gives the quadrature component. In a field of peak amplitude E_0 the energy lost per radian is $\epsilon_0 \chi''(\omega) E_0^2/2$, and the power lost is $\sigma(\omega) E_0^2/2$, and this defines the alternating current (a.c.) conductivity

$$\sigma(\omega) = \sigma_0 + \epsilon_0 \omega \chi''(\omega) \quad (6)$$

showing the relationship between a.c. conductivity and dielectric loss, with the direct current (d.c.) conductivity, σ_0 , being included. Equation (5) shows that $\chi'(\omega)$ and $\chi''(\omega)$ are inter-related and they are, in fact, Hilbert transforms¹ of one another, known in this context as the Kramers-Kronig relations which are valid in the most general conditions, subject only to the linearity of response. It follows that any one of the three functions $\chi'(\omega)$, $\chi''(\omega)$ and $f(t)$ fully determines the response of the system and the other two may be derived from it.

Mechanisms of polarisation

Of the several possible polarisation mechanisms, induced atomic, or electronic, and also ionic lattice polarisations, respond so rapidly, that they are effectively instantaneous below GHz frequencies, contributing a purely real value, ϵ_∞ , to the permittivity. Permanent molecular dipoles, ionic defects of dipolar type (vacancy-interstitial pairs) and also slowly mobile hopping charge carriers of electronic, polaronic or ionic nature produce much slower responses so that the permittivity of a medium containing some or all of these may be written in the form

$$\epsilon(\omega) = \epsilon_\infty + \epsilon_0 \sum_\alpha \chi_\alpha(\omega) \quad (7)$$

where the index α labels the various mechanisms and χ_α are complex in the sense of equation (5).

*Chelsea College, University of London, Pulton Place, London SW6.

Fig. 1 A compilation of dielectric loss data for a range of polymeric materials. The points marked with different symbols correspond to data taken at different temperatures and transposed laterally to make the loss peaks coincide. The vertical scale is $\log \chi''$ and the consecutive graphs are displaced vertically for clarity. The numbers indicate slopes of the straight line portions of the graphs. *a*, Low temperature data for polychloroprene; *b*, PCTFE 12% crystalline; *c*, polyethylene terephthalate; *d*, polymethyl methacrylate; *e*, high temperature data for polychloroprene; *f*, polyethyl methacrylate; *g*, polydian carbonate; *h*, polyvinyl acetate. The shape of a pure Debye peak is also included for comparison. (From ref. 5).

Dipolar responses

The classical case of dielectric response is that of a set of identical non-interacting dipoles free to rotate against some viscous resistance in a fluid-like medium—Debye's original model³—or 'jumping' by thermal excitation between two preferred orientations separated by a potential barrier—a situation more likely to be found in solids. The Debye susceptibility is given by the expression

$$\chi(\omega) \propto \frac{1}{1+i\omega\tau} = \frac{1}{1+\omega^2\tau^2} - i \frac{\omega\tau}{1+\omega^2\tau^2} \quad (8)$$

where the relaxation time τ is generally thermally activated and the loss peak frequency varies with temperature as

$$\omega_p = 1/\tau = \nu_0 \exp(-W/kT) \quad (9)$$

where ν_0 is some 'attempt-to-jump' frequency and W is an activation energy. The loss peak given by the second term in equation (8) is symmetric on a $\log \omega$ scale and has a width at half height of 1.144 decades.

Typical examples of dipolar behaviour may be found in many polar polymers³ in which the dipolar species may be well characterised both in type and in density. However, the dielectric loss in real polymers departs strongly from the Debye response and some examples are shown in Fig. 1 giving data corresponding to various temperatures 'normalised' by the customary displacement along the frequency axis to align the peaks^{4,5}. The Debye response is shown for comparison. The sharper α peaks are observed above the glass transition temperature, T_g and have approximately twice the width of Debye, the lower-temperature β peaks are hardly recognisable.

The main point I wish to emphasise here is that the post-peak response of all these materials may be characterised by the relation

Fig. 2 The compilation of a.c. conductivity data for a range of materials arranged on a common $\log f$ basis (in Hertz) but displaced vertically along the $\log \sigma$ axis for clarity. Data sets denoted by one letter are on a common $\log \sigma$ scale. *a*, Single crystal silicon in the impurity hopping range by electrons at (bottom to top) 3.0, 4.2, 8.0 and 12.0 K. (ref. 13); *b*, single crystal β alumina at 77 and 87 K—a classic fast-ion conductor by Na^+ ion movement¹⁴; *c*, glow-discharge deposited amorphous silicon in the temperature range 84–295 K (ref. 15); *d*, a range of chalcogenide glasses at 293 K, top to bottom: Sb_2S_3 , $\text{Sb}_{30}\text{As}_{10}\text{S}_{60}$, $\text{Sb}_{30}\text{As}_{30}\text{S}_{40}$, As_2S_3 , $\text{Sb}_{10}\text{As}_{30}\text{S}_{60}$ (ref. 16); *e*, single crystal anthracene at 294 K with 1 M saline solution as contact—two sets of measurements are shown (not resolvable on the scale of the present diagram)¹⁷; *f*, single crystal anthracene (—x—x—) and evaporated β carotene (---) at 294 K (ref. 18). The two sets of data are on corresponding $\log \sigma$ scale, showing the close similarity of the results in the a.c. range, with significant departures in the d.c. levels. These results show the superposition of a very shallow peak at 10^6 Hz with an underlying trend $\sigma \propto \omega$; *g*, trinitrofluorone-polyvinyl carbazole (TNF PVK) (ref. 19); *h*, three glasses (a) 50 P_2O_5 –50 FeO , (b) 50 P_2O_5 –40 FeO –10 CaO , (c) 50 P_2O_5 –25 FeO –25 CaO : room temperature²⁰; *i*, 80 V_2O_5 –20 P_2O_5 glass at three temperatures²¹; *j*, evaporated amorphous SiO_x (silicon monoxide) in the range of temperature (bottom to top) 211–297 K (ref. 22); *k*, stearic acid 9-layer film between Al and Au electrodes in the dark ($\square\square$) and in the presence of ultraviolet light ($++$) (ref. 23); *l*, three amorphous samples (top to bottom) As_2Se_3 , Se and As_2S_3 . The measurements, taken at 300 K are believed to be those of the bulk material and not to be influenced by the electrodes²⁴; *m*, two samples of As_2Se_3 at room temperature²⁵ extending to far-infrared frequencies and showing a steeply rising ω^2 region above 10 GHz, characteristic of lattice vibrational processes.

$$\chi''(\omega) \propto \omega^{n-1} \quad \text{with } n < 1 \quad (10)$$

or by a superposition of two such functions with the higher-frequency component having values of n closer to unity. The exponents n are weakly temperature dependent, decreasing with increasing temperature. Many polymeric materials, polar as well as non-polar, show very flat losses over many decades of frequency, with superimposed very weak peaks, a behaviour consistent with $n \approx 1$ and not at all compatible with Debye-like responses.

A particularly interesting class of dipolar materials are clathrates⁶ in which 'guest' molecules are individually enclosed in cages of H_2O molecules having almost spherical symmetry. These materials show the same type of 'non-Debye' behaviour given by equation (10). There are also examples of solutions of polar molecules in non-polar solvents giving the same response not consistent with any obvious interpretation⁷.

Carrier polarisation

This category covers a very wide range of mechanisms and materials, the one common feature being that the charge carriers involved move by discontinuous hopping movements between localised sites—they may be electrons, polarons or various ions. Electrons or polarons normally hop between sites randomly distributed in space and in energy⁸ but it is almost impossible to distinguish between them experimentally. The d.c. conductivity is determined by the most difficult hops in percolation paths between the two electrodes, a.c. conductivity is thought to arise from more limited displacements, with two-centre hopping said to constitute the high-frequency limit. By contrast, ions move typically over much smaller, nearest-neighbour distances and it is particularly interesting to note, therefore, that neither the magnitude of the a.c. conductivity, its activation energy nor, in particular, its frequency dependence can be taken as reliable guides to the nature of the dominant carrier responsible for polarisation.

Electronic hopping is associated primarily with the class of amorphous and glassy semiconductors⁹⁻¹² which have received a good deal of experimental and theoretical attention in the last fifteen years or so. Figure 2 shows a selection of conductivity data for several of these materials¹³⁻²⁶, plotted on a common scale of $\log f$ and displaced vertically along the $\log \sigma$ (ω) scale for clarity. The same figure also shows some other materials not necessarily associated with glassy electronic semiconductors, notably β alumina, the classic ionic conductor, as well as anthracene and β carotene.

The frequency dependence of the electrical conductivity of all these very different materials may be represented by the expression

$$\sigma(\omega) \propto \omega^n \quad n \leq 1 \quad (11)$$

Fig. 3 The compilation of the data for the a.c. conductivity of Fig. 2 on a common scale of $\log \sigma$ ($\Omega \text{ cm}$)⁻¹ showing the relatively narrow range of a.c. conductivity for a very wide range of materials. The upper and lower sloping chain-dotted lines correspond, respectively, to dielectric loss ($\chi'' = 10$ and 10^{-3} , independent of frequency).

which is fully equivalent to (10). Most of the samples show no sign of d.c. conductivity or even of any deviation from a single value of the exponent n , while some show a smaller value of n at lower frequencies—*b*, *c* and *k*—yet others give a d.c. or near-d.c. dependence—*j* and *k*. The temperature dependence of the a.c. conductivity is generally much weaker than that of the corresponding σ_0 , the exponent n showing the same trend as in Fig. 1. Both β carotene and anthracene reveal a shallow loss peak superimposed on the general trend and centred on 1 MHz. The characteristic feature of all the other data is the absence of any evidence of loss peaks which would correspond to slopes significantly in excess of unity on the low-frequency side.

The numerical values of the exponents n for the different materials are listed in Table 1. The one conclusion that may be drawn is that values in the range $0.5 < n < 0.9$ are closely associated with proven carrier transport: hopping electrons in crystalline and amorphous silicon, SiO_x and stearic acid, the response of which is shown in more detail in Fig. 4. In this case it has been established that the values of n close to unity are to be associated with the 'lattice' response²⁴. This distinction between 'lattice' and 'carrier' responses corresponding, respectively, to 'intrinsic', that is irreducible, and

Table 1 Numerical values of the exponent n for different materials in Fig. 2

'extrinsic' processes due to some impurities or injected carriers, may prove to be a useful diagnostic tool in the assessment of dielectric materials²⁷.

The expanded data of Fig. 2 are replotted again in Fig. 3 but this time on a common scale of $\log \sigma$, in order to bring out the very narrow range of values of $\sigma(\omega)$ at any particular frequency. The two sloping chain-dotted lines correspond to $\chi'' = 10$ and 10^{-3} independent of frequency, that is they cover four powers of ten and virtually all the data fall in this range, while a large majority actually fit into two decades, between 1 and 10^{-2} . This narrow range of the observed values of the loss was pointed out by me some time ago²², when I speculated on the possible role of contacts, as I found it difficult to believe that all these diverse materials should show such similar bulk properties. However, I do not think that there can be much doubt about the fact that we are dealing with genuine bulk properties and this is further confirmed by the very similar range of absolute values of dielectric loss in many polymeric solids.

Other dielectric materials

Many more examples may be quoted of dielectric behaviour following the general trend given by equations (10) and (11), with either a loss peak or a trend towards d.c. at low frequencies and a few of these will be mentioned here: sputtered films of lead-zinc-niobate and other materials^{29,30}; electrolytic capacitors of Al or Ta on plain foil, deeply etched foil or sintered porous bodies, thus proving that the geometrical configuration of the films has no significant influence on the response (F. Meca, personal communication); aqueous solutions of alkali halides, for example LiCl (ref. 31); dry sand follows equation (11) over seven decades with $n = 0.84$ (ref. 32); a wide range of composite dielectric materials such as rubbers, ceramics, sintered alumina, insulating glasses^{33,34}, and so on.

The same 'flat' frequency dependence of loss is found in some ferro-electric materials such as lead-zirconate-titanate and similar ceramics and likewise triglycene sulphate (TGS). In TGS the results are particularly striking since the Curie temperature, T_c , is at 50 °C and both χ'' and χ' show a singularity at T_c as functions of T , both being fairly flat in frequency at all temperatures, while the ratio χ''/χ' remains almost constant across the ferro-electric-para-electric transition (D.C. Dube, personal communication).

Very thin films also sometimes display the response characterised by equation (10). It is found down to monomolecular layers of, for example, stearic acid²⁶. Silicon P-N junctions form capacitors in one of the most perfect dielectrics known and it is therefore particularly interesting that their loss shows very shallow peaks resembling the flatter examples of dipolar losses in Fig. 1 (ref. 35). Interesting dielectric properties are shown by the solid electrolytes, defect solids in which ions show very high mobilities owing to the fact that there is no need to create the vacancies normally required for ionic conduction³⁶⁻³⁸. Many of these materials show negligible electronic conduction. Their electrical properties are commonly measured as complex impedance over a range of frequencies and the complex impedance diagrams are circular arcs with centres depressed below the real axis. I have pointed out that this is a direct consequence of a frequency-dependent conductivity of the type given by equation (11) and detailed studies confirm that this behaviour is found in a wide range of materials, single crystalline such as the β alumina in Fig. 2, polycrystalline and glassy (J. M. Reau, personal communication).

Time-domain response

Subject to the linearity of response, for example absence of charge injection¹⁰, the response function $f(t)$, equations (2) and (5), corresponding to the 'non-Debye' response given by equation (10) is

$$f(t) \propto t^{-n} \quad (12)$$

and most dielectric materials show this form of current response to step-function excitation which is known as the Curie-von Schweidler law⁴¹⁻⁴⁴. Where a loss peak is present, as in Fig. 1, the response becomes⁴⁵

$$f(t) \propto [(\omega_p t)^{1+m} + (\omega_p t)^n]^{-1} \quad (13)$$

where $m < 1$, and this is represented in Fig. 5. Physically this corresponds to two consecutive processes, the Curie-von Schweidler law with the negative exponent $n < 1$ for times $t < 1/\omega_p$, and a similar law but with the negative exponent $1+m$ in excess of unity at times $t > 1/\omega_p$.

The 'universal' law of dielectric response

The dielectric response of almost all solid dielectrics—and of some liquid ones as well—may be represented by either of

Fig. 5 Current response under step-function excitation according to equation (13), with $n = 0.7$ and $k = 1+m = 1.2, 1.3$ and 1.5 . The slope becomes equal to -1 at $\omega_p t = 1$. The Debye response $\exp(-\omega_p t)$ is also shown for comparison. From ref. 45.

the two diagrams of Fig. 6; *a* represents the classical dipolar response modified by the experimentally observed broadening, while Fig. 6*b* represents the 'carrier' dominated low-frequency response. The common feature is the extended range of frequencies over which the loss obeys the law given by equation (10), which has the unique property that its Kramers-Kronig transform has the same functional form but for a constant factor, so that the real part of susceptibility is the same function of frequency and the ratio

$$\chi''(\omega)/\chi'(\omega) = \cot(n\pi/2) = \text{const.} \quad (14)$$

independent of frequency. This is in complete contrast with the Debye behaviour for which this ratio is equal to $\omega\tau$.

I define this as the 'universal' dielectric response and its range of validity extends from ω_p , in those cases where it is observable, to the onset of phonon and quantum phenomena at around 1–10 GHz. In many materials we have an unbroken range of six to ten decades of frequency, while in others it is easy to recognise the superposition of two mechanisms of this type but with different values of n .

As well as the range of frequencies, what is most remarkable is the range of material for which this universal law is applicable:

All structural forms: single crystal, polycrystalline, amorphous and glassy, aggregates; **all types of chemical bonds:** covalent, ionic, molecular; **all possible types of polarising species:** dipoles, hopping electrons, ions; **a wide range of geometrical configurations:** 'bulk' samples, thin films down to molecular dimensions, intricate geometries.

These facts have been known, albeit perhaps not in their full extent, for many years, some going back seventy years and

Fig. 6 Schematic representation of the two types of dielectric response in the frequency domain, plotted as the logarithm of the real and imaginary components of the susceptibility against the logarithm of frequency. Both show the 'universal' behaviour with ω^{n-1} dependence at the higher frequencies. Diagram (*a*) corresponds to a dipole-dominated response, with a loss peak at the ω_p , diagram (*b*) gives case carrier-dominated low-frequency response with a different value of the exponent $n' < n$. The scale markers signify units on the logarithmic scales.

many attempts have been made to interpret this behaviour in terms of some model or other, according to the particular class of materials under consideration. A more detailed critique of this will be found elsewhere (A.K.J., to be published) and I have to limit the discussion to bare minimum here. The dipolar responses are frequently interpreted in terms of distributions of Debye-like relaxation processes, although it is difficult to see how the required range of τ , covering eight to ten decades of time can be justified in any particular system. Hopping electrons and polarons have been the subject of very extensive treatments^{46–55}, in terms of percolation theories and jump probabilities between states randomly distributed in space and in energy. While these treatments are very plausible and mathematically much more refined than many other dielectric theories, it is difficult to believe that the range of materials shown in Fig. 3 should exhibit such closely similar absolute values, given the wide range of physical hopping parameters likely to be involved. Moreover, the applicability of the universal law down to the thinnest samples presents some difficulties in this approach, where consecutive hops are needed to give the observed characteristics.

Ionic conductors are being interpreted in terms of some distributions of 'relaxation times' which are not specified and therefore are difficult to criticise. Alternatively, it is postulated that the bulk behaves in a frequency-independent manner, that is as an ideal dielectric in parallel with an ideal conductance, while the entire frequency dependence derives from limitation of ion supply across interfacial barriers^{56,57} whose transmission coefficients have to be postulated according to need. However, these coefficients are not separately measurable so they remain conjectural and, in any case, it is difficult to explain by this means values of n in the range 0.5–0.8 typically found in many ionic conductors.

Attempts have been made to move away from Debye philosophy by introducing diffusion-limited relaxations^{58–60}, but apart from a certain lack of physical clarity regarding the mechanism, it is only possible to explain by this means values of n close to 0.5. Diffusion is also at the base of the Warburg impedance mechanism⁶¹ commonly used in liquid electrolyte problems and often invoked in solid electrolytes, although its applicability here is suspect since it requires the presence of two mobile ionic species with opposite signs of charge.

Many analytical attempts have been introduced to explain the time-domain Curie-von Schweidler law in terms of correlation functions^{62–64} but again one is left with an essential arbitrariness at some stage in the choice of the functions required to give agreement with experiment.

Many-body interactions

I suggest that, faced with the sheer universality of the observed behaviour, in terms not only of a common frequency dependence but, not least, of a narrow range of absolute values of loss in very diverse materials, one is left with the overriding impression of an essential insufficiency of all these different interpretations and the need for an entirely fresh approach, based on a principle of sufficient inherent generality to be capable of embracing all the materials under consideration.

What is even more remarkable is that the universality does not stop with dielectric responses—it is well established in the case of mechanical moduli of disordered systems, both polymeric⁶⁵ and metallic. Here I refer not to the well known fact that dielectric and mechanical loss peaks follow similar trends⁶⁶, but to the much more significant, in the present context, relaxation law beyond the peaks which is of the form (10), even though the exponent n is not the same in both cases. There is also a well established equivalent of the Curie-von Schweidler law in mechanical relaxation.

There is even some evidence, although much less well documented, that magnetic losses in many ferrites follow an almost frequency-independent trend at low frequencies⁶⁷, thereby tentatively extending the observed universality of the dynamic relaxation to the third fundamental stress-strain relationship.

I have suggested that the universally observed constancy of the ratio (14) implies the physically elementary fact that⁵

$$\frac{\text{energy lost per radian}}{\text{energy stored}} = \cot(\pi/2) = \text{const.} \quad (15)$$

independently of frequency and that this should be taken as the universal criterion of dielectric, mechanical and, possibly even magnetic relaxations in solids.

In the case of dielectrics, I have noted that the one general property of all systems under consideration is that the polarisation is due to discontinuously hopping electrons or ions, or to likewise discontinuously jumping dipoles and I have introduced the simple concept of screening of charges and dipoles. This screening is the result of many-body interactions and has the simple and universal property that it adjusts 'slowly' to the 'fast', that is effectively discontinuous, jumps of individual particles or dipoles. I have suggested that this 'dual' time scale leads to the property (15) and, therefore, inescapably through the Kramers-Kronig relations, to the universal frequency dependence (10).

The introduction of many-body formalism into the interpretation of the universal dielectric response of solids does find a striking parallel in the theory of X-ray singularities in metals⁶⁸ and also in the problem of infrared divergence⁶⁹, both leading to theoretical expressions for time-dependent responses resulting from many-body interactions which are identical with the Curie-von Schweidler law. While the time scales in question are separated by many orders of magnitude, the similarity of the resulting power-law dependence on time invites a detailed examination of the validity of this approach. (This study is currently being carried out in collaboration with K. L. Ngai of the Naval Research Laboratory, Washington DC.)

An attempt to explain the conductivity law (11) in terms of many-body interactions was made by Pollak and Pike⁷⁰, who associated it with the low-temperature specific heat anomaly in glasses. An even earlier suggestion to this effect was made by Garton⁷¹ but seems to have been largely forgotten. These are clear pointers in the direction of many-body interactions being an acceptable explanation of the universal dielectric response, but a great deal of work requires to be done before the situation could be regarded as clarified. I am suggesting that the dielectric response provides us with an 'analogue solution' of a many-body interaction and this may prove valuable in the theoretical studies. In addition, I believe that the physical significance of the energy criterion (15) in the frequency domain should not be underestimated—it may give us a vital insight into the processes in question, mechanical no less than dielectric. My screened-hopping model is based on this criterion, but there may exist other possible ones.

The loss peak and other low-frequency processes

To the extent to which we may accept the many-body approach, through the energy criterion, as explaining the universal response in the frequency domain, equation (10), in the range in which it is valid, we need an interpretation of the loss peaks which are found in dipolar systems. I suggest that their interpretation in the accepted 'distribution' argument is not very satisfactory, not least in view of the fact that the pre-exponential factor ν_0 in equation (9) is found to cover the prodigious but physically meaningless range 10^3 to 10^{30} Hz, for both mechanical and dielectric cases (C. Lacabanne, personal communication), where 10^{13} would have been expected as a 'lattice' frequency.

I have suggested that a very simple explanation of loss peaks in the context of our many-body approach may be found in the time-domain picture of Fig. 5 (ref. 45). The loss peak arises from the transition in the time-domain response after a step function excitation, from a 'primary' relaxation process with $n < 1$, to a 'secondary' process with a larger exponent which completes the adjustment to the steady state. The primary

process is the Curie-von Schweidler law, corresponding to the energy criterion in the frequency domain. The secondary process is not at present understood, although its physical necessity in the case of dipolar polarisation follows from the requirement to have a finite total charge in the system. There is, however, nothing inherently implausible in a concept of a succession of two different processes in a many-body relaxation. The important point is that the loss peak is the resultant of this transition from one process to another and that the loss peak frequency is determined solely by the time of transition. That this time should be activated with a well defined energy, as is normally observed, seems perfectly understandable—it must be related to some thermal processes, but there is no need to associate the pre-exponential factor ν_0 with any particular 'lattice' frequency, as is the case in the Debye philosophy.

The apparent absence of loss peaks in carrier-dominated situations, as well as the presence in some cases of strong low-frequency dispersions obeying an approximately $1/\omega$ law for both $\chi'(\omega)$ and $\chi''(\omega)$ presents an interesting problem but lies beyond the scope of the present treatment.

Conclusions

Experimental evidence leads to the conclusion that there exists for a wide range of solids a universality of dielectric behaviour demanding a much more unified interpretation than the hitherto accepted specialised approaches which are somewhat arbitrary and which are tailored to the various separate classes of materials. Moreover, the universality extends beyond the dielectric properties—it is well established in the case of dynamic mechanical response of glassy solids and there is tentative evidence for its presence in magnetic response.

I suggest that the unified approach should be based on the indisputable common property of all condensed matter—the many-body interactions between its constituent parts.

The otherwise somewhat arbitrary functional form of the universal response has the unique property in the frequency domain that the ratio of energy lost per cycle to energy stored is independent of frequency and I am proposing to make this the physical criterion of all dielectric responses. The corresponding time dependences are identical with those found theoretically for a number of many-body interactions, such as the X-ray singularity and the infrared anomaly.

In the dielectric case this criterion is satisfied by mutual screening of hopping charges or dipoles and is based on the relatively slow adjustment of screening in comparison with the practically instantaneous hopping transitions of individual charges or dipoles. A new interpretation is proposed in the same framework of the peaks of loss observed in dipolar systems.

This work was carried out under financial assistance from the Science Research Council and from Chelsea College. I am grateful to many colleagues for helpful criticisms and to some for permission to quote unpublished information. I am particularly indebted to Dr. K. L. Ngai for his comments on the many-body interactions.

Turning points in Phanerozoic history

Martin A. Whyte

Department of Geology, University of Sheffield, Sheffield, UK

During the last 450 Myr there has been concomitant variation in the Earth's rotation rate, the polarity bias of the geomagnetic field, the amount of activity at ocean ridges, sea level and climate. At turning points when trends in the variables reverse themselves, climatic instabilities have disrupted biological ecosystems and led to mass extinctions.

ONE of the most interesting cooperative efforts within the earth sciences is that between palaeontologists and geophysicists in which skeletal growth rhythms recorded in fossils are used to elucidate the Earth's rotational history. It has been established that the rotation rate has fluctuated during the Phanerozoic. This synthesis suggests that subtle long term variations in other parameters can be correlated with changes in rotation rate.

Rotational history

The modification of skeletal growth by external environmental cycles can produce within a shell a detailed record of daily, fortnightly, monthly and annual events. The potential of such structures was first fully realised by Wells¹ who made counts on Middle Devonian corals which indicated that at that time, 390 Myr, there were 400 solar days in the year. As Wells^{1,2} appreciated the slowing down of the Earth's rate of rotation, which this result indicated, corroborated the geophysical prediction that the lunar tidal torque has a braking effect by which angular momentum is transferred from the Earth to the Moon. Soon afterwards Scrutton³ who also used Middle Devonian corals, made counts indicating that there had been 30.6 d in the synodic month and Runcorn⁴ showed how this pair of observations could be used to test for possible changes

in the Earth's moment of inertia. Runcorn's analysis, though probably unreliable due to the statistical uncertainty inherent in the original data^{5,6}, suggested that any changes in the Earth's moment of inertia must have been small and subsequent workers have generally accepted tidal friction as the operative mechanism in the rotation deceleration. However, as more palaeontological data became available it became evident^{7,8} that there had not been a uniform rate of decrease in spin velocity and a significant recent advance was made by Creer⁹ who recognised that there have been periods of earth history when the Earth's rate of rotation has accelerated (Fig. 1). During the last 500 Myr these periods of acceleration have alternated with periods of deceleration of spin velocity and there are turning points of two types, firstly spin maxima at transitions from acceleration to deceleration and secondly spin minima at transitions from deceleration to acceleration. Revised estimates indicate that spin maxima occurred 65 Myr (end Cretaceous) and 375 Myr (middle Upper Devonian) ago and that spin minima occurred 235 Myr (end Permian) and 445 Myr (late Ordovician) ago (Fig. 1). The periods of acceleration recognised by Creer⁹ cannot be easily explained by tidal friction alone and suggest that some additional mechanism or mechanisms must be operating. This additional component seems to be a fluctuating system superimposed on a general trend for deceleration of spin velocity which presumably represents the effects of tidal friction (Fig. 1).

Creer⁹ also recognised that the turning points were closely associated in time with periods of instability in the palaeomagnetic field (Fig. 1). While periods of rotational acceleration are characterised by a predominance of normal polarity and periods of rotational deceleration are characterised by a predominance of reversed polarity, turning points are associated with phases of mixed polarity which show no obvious polarity bias and which may also have

Fig. 1 Aspects of Phanerozoic history. *a*, Number of solar days per month (modified from Creer⁴ using palaeontological data⁷⁻¹³). *b*, Number of solar days per year (modified from Creer⁴; using palaeontological data 1, 2, 8, 14; the dashed line is extrapolated from the present rate of deceleration¹⁵). *c*, Percentage of reversed polarity (based on Creer⁴). *d*, Number of higher taxa, of all biological groups, becoming extinct (based on Cutbill and Funnell¹⁶). *e*, Percentage flooding of the N. American craton (based on Wise¹⁷; the dashed curve is a period-by-period smoothed curve). *f*, Temperature of high latitude marine waters (based on Savin *et al.*¹⁸). *g*, Occurrence of ice ages (refs 43, 45-47).

had high reversal frequencies. A close link between the Earth's rotation and its magnetic field has long been recognised: there seems to have been a near alignment of rotational and dipole axes throughout time and it has been suggested that the influence of rotational forces on the fluid outer core may be vital to the generation of the magnetic field¹⁶. On the other hand the irregular decade fluctuations in the Earth's rate of rotation have been correlated with changes in the geomagnetic field and attributed to the transfer of angular momentum between the core and the mantle¹⁷. The core-mantle coupling is generally interpreted as being an electromagnetic effect though viscous forces and topographic features of the boundary may also be important¹⁸. Though extraterrestrial sources cannot be altogether discounted, the geologically detectable rotational and magnetic fluctuations are most probably due either to changes in the Earth's moment of inertia¹⁹ or to an internal redistribution of angular momentum¹⁸ and it is a great pity that the palaeontological data are not yet sufficiently precise to allow elimination of one or other of these possibilities using an extended form of Runcorn's analysis.

In the middle Carboniferous and again during the Late

Jurassic and early Cretaceous there were periods in which the palaeomagnetic field became moderately disturbed¹⁹. However, unlike the conditions at turning points, the field retained an overall polarity bias and there was no associated switch in the direction of the predominant polarity. One might predict that these events were accompanied by slight inflections in the rate of change of the Earth's rotation but the palaeontological data are at present too scanty to allow this possibility to be tested. These episodes could perhaps be interpreted as aborted turning points and it is worth noting that they are followed by the most important Phanerozoic quiet intervals namely the Permian-Carboniferous (Kiaman) Reversed Interval and the Cretaceous (Mercanton) Normal Interval. The Cenozoic magnetic field has apparently always been relatively unstable but there seems to have been within the last 10 Myr a change from a predominance of reversed polarity¹⁹ (Fig. 1) and during the same period there has also been an increase in the frequency of reversals²¹. Astronomical estimates of the present rate of secular deceleration give a value lower than that which seems to have operated during the last 65 Myr (Fig. 1) and this, together with the magnetic evidence, might indicate that we are at or close

to another spin minimum. Including this putative turning point and the two aborted ones it seems that turning points are separated by a characteristic time interval with an average length of 74 Myr.

Mass extinctions

Several investigations²² of Pleistocene deposits have noted a significant correlation between magnetic reversals and extinctions of fossil species and these results are consistent with Uffen's hypothesis²³ that during reversals biological systems would be adversely affected by increased radiation doses. Simpson²⁴ extended this hypothesis to suggest a correlation between mass extinctions and periods of high reversal frequency and this is strongly supported by Creer's data⁵ since the major mass extinctions in the late Ordovician, middle Upper Devonian, end Permian and end Cretaceous coincide with turning points (Fig. 1). Considerable doubt²⁵⁻²⁷ has been cast on whether a magnetic reversal alone would cause a sufficient increase in radiation fluxes but it has recently been suggested that if a solar flare occurs during a reversal it might cause the ozone layer, which shields the Earth's surface from ultraviolet radiation, to become depleted²⁸. Alternative theories²² have suggested a direct relationship between the magnetic field and the well-being of organisms or an indirect relationship through climatic effects.

Correlations between climatic changes and changes in the intensity of the geomagnetic field have been demonstrated and possible linking mechanisms have been discussed^{29,30}. As previously noted there is a correlation between geomagnetic field intensity and rotation rate¹⁷ and Lambeck and Cazenave⁶⁷ have detected a correlation between climate and rotation rate. They have however calculated that the magnitude of the rotational changes is not sufficient to fully explain the associated climatic effects. It is suggested here that magnetic fluctuations cause climatic effects partly as a direct effect and partly through the associated changes in spin velocity, and that the magnetic instabilities at turning points cause climatic instabilities.

The general pattern of mass extinctions is for the communities of stable environments with their great diversity of specialised member species to be most severely affected³¹. Thus offshore benthic communities were more affected than onshore benthic communities^{32,33} and that most complex of all marine associations, the reef community, underwent at each mass extinction a dramatic collapse from which it often took millions of years to recover^{34,35}. The climatic instabilities at turning points were thus probably only triggers, which by causing a few extinctions and/or a reduction in primary production, created a house of cards effect leading to the collapse of ecosystems³¹.

Neither the mid-Carboniferous nor the end Jurassic events were associated with abnormally high extinction rates but Late Pleistocene and Recent extinctions, though dominantly affecting large (that is, specialised) terrestrial vertebrates, are well documented^{36,37}. While man must in all probability take a large share of the blame for these extinctions it may well be that he is only exacerbating an unstable situation.

Climatic history

Apart from the possible climatic instability at turning points the periods of acceleration seem to be characterised by climatic amelioration while periods of deceleration are characterised by climatic deterioration. Thus spin minima were preceded by ice ages with marked seasonal and latitudinal climatic contrast (Fig. 1) while spin maxima were preceded by climatic optima with an equable warm climate. Isotopic evidence^{38,40} (Fig. 1) shows clearly the temperature decline that has taken place, especially at high

latitudes, during the Tertiary. Mesozoic isotope data^{41,42} are less well controlled but indicate warm temperatures even at high latitudes and, though there were fluctuations a trend for temperature increase up to the Late Cretaceous optimum about 80 Myr ago. The Permo-Carboniferous and the Late Ordovician Ice Ages are well documented⁴³ and a recent synthesis³⁹ has suggested that there was a reduction in climatic gradients during the Silurian and Devonian. The Cretaceous optimum gave rise to the acme of reef development by scleractinian corals and the early Upper Devonian optimum was similarly the acme of the tabulate coral and stromatoporoid reef assemblage³⁴. The scleractinia as a group have declined during the Tertiary³⁴ and the poor representation of reef corals in the Carboniferous and Permian may also be a climatic effect. As in the Permian, bryozoans and sponges are an important element of Ordovician carbonate build-up³⁴ formed during a phase of climatic deterioration. A pre-mass extinction diversification has been detected in the Cretaceous and in the Devonian but not in the Permian⁴⁴ which may be a consequence of its different climatic regime.

It is interesting to note that Upper Palaeozoic ice sheets seem to have developed before the mid-Carboniferous aborted event⁴⁵⁻⁴⁷ and this may explain the long time span of the Permo-Carboniferous Ice Age.

Climate and eustasy

Though a change in the length of the day would, for instance, cause a small change in the diurnal temperature inequality⁴⁸, the overall trend evident in the rotational data suggests that the link between climate and spin velocity is not a direct one. Rotational changes may have been accompanied by other changes in the Earth's orbit, which could also have caused slight climatic effects, but the most important control on climate would seem to be sea level⁴⁹. Hays and Pitman postulated⁴⁹ that increased climatic contrast will result from eustatic lowering of sea level and that eustatic raising of sea level will cause 'moderation and stabilisation of climate'. The global Mesozoic transgression and the subsequent Cainozoic regression are well documented⁴⁹⁻⁵³ (Fig. 1). Sea level changes in the Palaeozoic are less clear and estimates based on N. American data⁵⁴ are clearly affected by tectonic events in the Appalachians. Cruder curves⁵³ (Fig. 1) suggest that there may have been overall transgression from the Late Ordovician to the Late Devonian followed by a regression into the end of the Permian. The Ashgill regression⁵⁴ and the widespread Ordovician-Silurian unconformity⁵⁵ represent the effects of the Late Ordovician eustatic minimum and in the Devonian a series of increasingly penetrative transgressions, which reach a maximum in the Late Devonian, have been recognised⁵⁶. Ice ages are thus a consequence of the increased climatic contrast resulting from regression but the exact timing of the onset of glaciation and the subsequent glacial history will be affected by other factors such as distribution of land masses, atmospheric turbidity and orbital motions. The association of glaciation with aridity³⁷ fits well with this theory and the increasing severity of Pleistocene glacial periods³⁷ can be linked to the continued decrease in sea level.

Though orogenic events can cause eustatic changes in sea level⁵² the dominant eustatic control seems to be the volume of oceanic ridges which is itself controlled by plate spreading rates (refs 49, 50, 58 and 59). Thus increased plate generation not only leads to an increasing volume of ocean ridges, a raising of sea level and an amelioration of climate but also correlates with an acceleration of mantle spin velocity and a predominance of normal polarity. Fast Cretaceous and slow Cenozoic spreading rates have been deduced for a number of ridge systems^{49,59}. More detailed work, despite uncertainties due to imprecision of the polarity time scale, suggests that Tertiary spreading rates

decreased¹ gradually up to about 10 to 15 Myr ago, since when there has been a slight increase in spreading rate^{60,61}. This may again suggest an impending turning point. The possible role of tidal and rotational forces in the plate tectonic mechanism has been discussed by several workers⁷²⁻⁷⁵, and, whether the relationships are causal or not, clearly ridge activity and changes in mantle spin velocity and predominant polarity are all related to some unifying process.

A coherent picture—but gaps still remain

Though much work needs to be done to improve our knowledge of the factors considered here, the data present a coherent picture. The Cenozoic, the Late Devonian to Permian and the Ordovician were times of deceleration of mantle spin velocity, of predominantly reversed polarity, of decreasing oceanic ridge activity, of global regression and of climatic deterioration leading to ice ages. By contrast in the Silurian to early Upper Devonian and in the Mesozoic there was acceleration of mantle spin velocity, predominance of normal polarity, increasing ocean ridge activity, global transgression and climatic amelioration. Turning points between phases of different type are marked by magnetic instability, possible climatic instability and by mass extinctions. Aborted turning points occurred in the middle Carboniferous and late Jurassic. Despite the many imperfections and biased nature of the geological record a subtle but distinctive background pattern can thus be detected in it. Whatever the cause may be this pattern is not only a record of surface processes but also of deep seated events some of which may even have taken place within the Earth's core.

This synthesis has a number of important implications. First, it places important new constraints on Earth models. These must be considered especially in discussions of the origin of the geomagnetic field, the mechanisms affecting the Earth's rotation and the driving force for plate tectonics. Second, the pattern can be applied to the Precambrian as an aid to understanding events and processes in the Proterozoic (Whyte, in preparation). Finally it allows us to make some simple predictions about the future geological history of the Earth. Thus not only do we seem to be at present at or close to a turning point (spin minimum) but we can predict that it will be followed by a period lasting about 60 to 90 Myr in which there will be rotational acceleration, a dominantly normal magnetic field, increasing ridge activity, global transgression and climatic amelioration.

Higher plant wax is demonstrated in aeolian dusts, showing the potential of aeolian transport in contributing significant amounts of terrestrial organic lipids to the marine environment over geological time periods.

The importance of aeolian particulate transport from the continents to the marine environment has been examined mainly through investigations of mineral and trace element contents of sediments and particulate matter in the water column^{1–4}. This transport mechanism, however, has been

Table 1 General aeolian dust collection data and sample descriptions

known since Darwin's time⁶. Biological material transported from the continents has been identified as discrete particles such as freshwater organisms, fungal hyphae, spores, plant fragments and insects^{3,4,6,7}. Terrigenous lipids such as the prevalent vascular plant waxes have been described as components of some aeolian dusts. Here we discuss the occurrence, isolation and characterisation of terrigenous lipids in aeolian dusts from the eastern Atlantic. Such lipids have also been found in aeolian dust from other oceanic areas⁸ and could be correlated with sedimentary lipids from deep-sea areas which have a large input of aeolian mineral components⁹. Lipids derived from terrigenous (higher plant) sources are primarily characterised by the distributions of the *n*-alkanes from *n*-C₂₅ to *n*-C₃₅ (odd carbon number predominance), the *n*-fatty acids from *n*-C₂₂ to *n*-C₃₂ (even carbon number predominance) and *n*-fatty alcohols from *n*-C₂₅ to *n*-C₃₂ (even carbon number predominance)⁹. Lipids derived from microbiota of either marine or lacustrine environments are characterised by the absence of these higher molecular weight homologues (> C₂₅) and the presence of *n*-alkanes ranging from *n*-C₁₃ to *n*-C₂₃ with a major maximum at C₁₇ and no significant carbon number predominance, and *n*-fatty acids ranging from *n*-C₁₂ to *n*-C₂₀ with a major maximum at C₁₆ and an even predominance⁹.

Collection and extraction of samples

Small dust samples were obtained from the research collection of the Department of Oceanography of the University of Liverpool. The samples had been stored in glass vials since completion of the inorganic analyses^{10,11}. The net-sampling procedure used here has been applied extensively for inorganic analyses of airborne particulates^{4,11,12}. The collection efficiency of the nets has been investigated in detail by various authors^{4,6,13} and it was found that such nets collect only about 50% of the < 2- μm size fraction and about 70% of the < 4- μm size fraction. The dust particles adhere to the net by concurrent wetting with sea spray and are washed salt-free afterwards⁹⁻¹².

The dust samples were extracted with two aliquots of toluene and methanol (3:1) for lipid analysis, and the extracts were concentrated on a rotary evaporator. After capillary gas chromatographic (GC) and gas chromatography-mass spectrometric (GC/MS) analyses all total extracts were treated with

diazomethane in ether and re-analysed by GC and GC/MS. Some extracts were further treated with *N,O*-bis-trimethyl silylacetamide (BSA) reagent to derivatise alcohols to trimethylsilyl (TMS) ethers and then subjected to GC and GC/MS analysis. The large sample extracts were separated by thin-layer chromatography (TLC) on silica gel with hexane-ether (9:1) as eluant into fractions corresponding to the retention times of hydrocarbons, esters and alcohols. These fractions were also subjected to instrumental analysis. The approximate yields of total lipids were estimated by weighing a 1-to-5- μl aliquot of total extract, after the solvent was allowed to evaporate, on a Cahn microbalance. These values were usually somewhat higher than those obtained by the sums of the integrations of the GC results from the hydrocarbon, acid ester and alcohol fractions. The instrumental analyses (GC and GC/MS) and the resultant detailed data have been described elsewhere^{8,9,14}.

The general collection data and descriptions for all samples are given in Table 1, and the sampling sites are shown on the map in Fig. 1. This sample suite represents a transect down the Atlantic Ocean from Spain past the tip (Cape of Good Hope) of South Africa (see Fig. 1). The beige Saharan dusts (samples 1 to 3) yielded relatively low amounts of solvent-soluble lipids. The dusts from the more tropical and the more vegetated environments (for example, samples 4 to 8) were grey to grey-brown and yielded larger amounts of solvent-soluble lipids.

The yields and analytical results for the *n*-alkanes and *n*-carboxylic acids are given in Table 2, together with some representative organic carbon values. The *n*-alkanes exhibited maxima at mainly *n*-C₂₅, *n*-C₃₁, and *n*-C₂₇, with strong odd-to-even carbon number predominances (see carbon preference index (CPI) in Table 2). The *n*-fatty acids maximised at *n*-C₁₆ and either *n*-C₂₄ or *n*-C₂₈, with strong even-to-odd carbon number predominances (see CPI in Table 2). The *n*-alkanes and *n*-fatty acids of all samples were distinguished from *iso*-, *anteiso*- and isoprenoidal compounds by coinjection of suitable standards on capillary GC, mass fragmentography and interpretation of individual low resolution mass spectra from GC/MS analyses. The *n*-alcohols exhibited a maximum at *n*-C₂₈, with a strong even-to-odd carbon number predominance (see CPI in Table 2). The distribution diagrams for all these lipid fractions can be found elsewhere¹⁴.

Fig. 1 Map showing the aeolian dust sampling locations and prevalent wind patterns (thick line, ship's track during aeolian dust collection; solid arrows, approximate extent of trade winds; dashed arrows, Harmattan wind).

Origin of samples

Sample 1 was taken off the coast of Morocco in the westerlies/north-east trades boundary zone and probably contains material derived from a variety of sources, including western Europe (for example, Spain) and the North African deserts. The extracted mixture consisted mainly of free fatty acids ranging from $n\text{-C}_{14}$ to $n\text{-C}_{20}$, with a maximum at $n\text{-C}_{16}$ and predominantly even homologues, and a minor amount of $n\text{-C}_{25}$ to $n\text{-C}_{33}$ alkanes. This acid distribution is a typical lacustrine and/or marine pattern⁹. Samples 2 and 3 consist mainly of the trade wind flux of Saharan material. The lipid yields were different for the two samples, but the distributions of homologues were essentially identical.

Samples 4 and 5 were collected off West Africa and probably represent mainly Saharan and West African material carried by the Harmattan winds (see Fig. 1)¹¹. Both lipid extracts exhibited distributions of homologues of predominantly $n\text{-C}_{25}$ to $n\text{-C}_{33}$ alkanes and $n\text{-C}_{22}$ to $n\text{-C}_{30}$ fatty acids, which are typical of higher plant wax¹⁵ and minor amounts of $n\text{-C}_{12}$ to $n\text{-C}_{20}$ fatty acids attributable to either a lacustrine or marine origin^{9,16}.

The remaining samples (6 to 10 and 12) represent fallout from the south-east trades (see Fig. 1), deriving material

mainly from the soils of southern Africa, the Namib and Kalahari deserts, and probably from the Lower Guinea area of Africa. Samples 9 and 10 were taken in the same area but at different seasonal times. The distributions of lipid homologues for these two samples were similar and the distributions of homologues for all the samples consisted of predominantly $n\text{-C}_{25}$ to $n\text{-C}_{33}$ alkanes and $n\text{-C}_{22}$ to $n\text{-C}_{30}$ fatty acids, and lesser amounts of $n\text{-C}_{12}$ to $n\text{-C}_{20}$ fatty acids.

The extracts of several samples (1, 6, 8 and 9) contained mono-unsaturated fatty acids (mainly $\text{C}_{18:1}$ and some $\text{C}_{16:1}$) in significant amounts. Trace amounts of triterpenoidal compounds were detected in the samples with a high plant wax component (such as 4, 5, 6, and 8) but not in the samples derived from more arid terrain (such as 1 to 3). Diterpenoidal compounds which have been proposed as terrigenous markers¹⁷ were not detected in any aeolian dust extracts examined thus far. Polynuclear aromatic hydrocarbons have also not been detected as any significant components (GC/MS detection limit approximately 0.1 p.p.m. per component). The problems of plasticiser and shipboard contamination were not serious and have been described in detail^{8,14,18}. Sample 11 represents an example of shipboard contamination where the lipids exhibited a general 'hump' distribution, typical of petroliferous material.

The n -alkanes, n -alkanoic acids and n -alcohols in the lipids of these aeolian dusts correlate well with terrigenous sources.

The n -alkanes observed in these dusts have essentially no homologues lower than about C_{22} and their distribution patterns corroborate a terrigenous origin from higher plant waxes^{15,19-21}. The extreme fragility of the plant wax protrusions has been described (ref. 22 and references cited therein). Wax particles are easily sloughed off from plant surfaces and can become airborne. There are not enough data points at this time to ascribe a significance or specific plant sources to the shifts of the maxima in the n -alkane distributions from $n\text{-C}_{27}$ in the North Atlantic (1), to $n\text{-C}_{27} \cong n\text{-C}_{29}$ (2, 3), to $n\text{-C}_{29}$ in the Inter-Tropical Convergence Zone (4 to 6), to $n\text{-C}_{29} \cong n\text{-C}_{31}$ (8), and to $n\text{-C}_{31}$ in the South Atlantic (9, 10) (see Table 2).

The n -alkanoic acid distributions of all the dusts exhibit a typically lacustrine and/or marine pattern, with maxima at C_{16} and superimposed on that a higher plant distribution pattern. Such fatty acid distributions have been described by many authors for sediments (see for example, ref. 23). This observation fits in part with Kolbe's proposal¹⁶ that aeolian dusts have a component derived from dessicated lacustrine muds. However, since the sampling nets were wet with sea-spray, some of the $n\text{-C}_{12}$ to $n\text{-C}_{20}$ fatty acids may also have a marine origin. Normal carboxylic acids with maxima at C_{24} or C_{26} and a strong even-to-odd predominance have been used as terrigenous

markers²⁴⁻²⁶ and these homologues from the dusts thus probably also represent a higher plant wax component. A shift of the maxima in the *n*-fatty acid distributions, analogous to the *n*-alkanes, was observed from *n*-C₂₄ in the North Atlantic samples to *n*-C₂₆ in the Mid- to South Atlantic samples. Again, no specific plant sources can be assigned to these limited data.

The higher molecular weight *n*-alcohol distributions observed for the dust samples (see Table 2) closely resemble the distributions of alcohols from plant wax. These consist of predominantly even-carbon-numbered homologues from *n*-C₁₆ to *n*-C₃₀, usually with a maximum at *n*-C₂₈^{15,21}. The presence of traces of triterpenoids in these dusts indicates that these compounds can be derived from a terrigenous source. The amounts of mono-unsaturated fatty acids (*n*-C_{16:1} and *n*-C_{18:1}) when considered with the distribution patterns of the saturated *n*-fatty acids < C₂₀, indicate a lacustrine and/or marine origin for these components. The presence of these labile compounds in the dusts also indicates that the destruction (photo-oxidation) of organic matter by ultraviolet radiation during transit is limited. The variations in the homologue distributions of the dust lipids from the relatively close geographical areas (for example, 9 and 10, 2 and 3, 5 and 6) may probably be accounted for by seasonal variations of plant source material and wind pattern change.

Anthropogenic components were found in dusts derived from urban and industrialised areas⁸. The hydrocarbons of aeolian dusts collected near urban centres have quite a different compound distribution, attributable mainly to petroleum product spillage and combustion (see for example refs 27, 28). The *n*-alkanes of urban air particulates are present as minor components as part of a general 'hump' typical of petroleum and they exhibit no carbon number predominance. On the other hand, the *n*-alkanes of the oceanic dusts are present as the major components and exhibit a very strong odd-to-even carbon number predominance. The sampling procedure using nets (meshes), however, does not collect aerosol particles, which can be major components of urban atmospheres (ref. 29 for example). Some oceanic dusts collected in proximities of urbanised areas (for example, inland sea off Japan⁸) also exhibit a 'hump' in the hydrocarbon fraction.

The sedimentation rates in the North Atlantic Ocean for the aeolian components off West Africa have been estimated to be about 0.6 mm per 1,000 yr (ref. 4). This figure is in good agreement with those reported by Goldberg and Griffin³⁰ for the equatorial regions of the Atlantic. Observed sedimentation rates adjacent to the Canary and Cape Verde Islands, based on ¹⁴C dates, range from 2-3 cm per 1,000 yr (ref. 31). A more recent input estimate of organic matter from dust to the ocean has been proposed³². It was found that during North African dust storms, extremely large amounts (> 10,000 µg m⁻³ at the coast) of dust are transported out to sea along about a 100 km stretch of coastline, thus also injecting a large organic component (about 20,000 tonnes of organic carbon per storm). Thus aeolian influx to the marine environment occurs in random major events and continuously in lower amounts.

The bulk of the lipid matter of aeolian dusts represents higher plant wax¹⁵ and fatty acids from lacustrine microbiota^{4,16} or possibly from sea-spray. It should be noted that the lipid yields for these samples are low when compared to the organic carbon contents of other samples from similar areas (see Table 2). No total carbon values could be determined for this sample suite. This difference may be partially due to a particulate carbon component from ships and a loss of volatile lipids during the analysis. Higher lipid yields against organic carbon were obtained for samples collected at the coastline of West Africa³². Work is proceeding to understand the budget of the influx of aeolian organic carbon compounds to the oceanic environment. It is, however, apparent that the input of aeolian material to certain sedimentary areas can be significant over geological time periods.

We thank Dr S. R. Aston and Mr D. Cross for providing some of the dust samples and Dr R. Philp for use of GC/MS facilities. Financial support in part from the National Aeronautics and Space Administration and the National Oceanographic and Atmospheric Administration is gratefully acknowledged.

letters to nature

Upper limits to X-ray emission from nova Vulpeculae 1976

Two recent optical novae have been observed to radiate a substantial flux of medium energy X rays (nova Monocerotis¹, and A1524-61 (ref. 2)), the X-ray luminosity in both cases reached a maximum at the same time as the optical

luminosity and was over 100 times greater. In contrast, an unsuccessful search was made by Hoffman *et al.*³ for X-ray emission from nova Cygni 1975 and the ratio of X-ray to optical luminosity in that case was found to be less than 10⁻⁴. Brecher and Morrison⁴ have suggested that the large differences in this ratio might be related to the rate of mass exchange in the binary system, believing that the X-ray

Table 1 X-ray upper limits

Mid-time (1976)	Orbit number	X-ray flux, L_x ($\text{erg cm}^{-2} \text{s}^{-1}$)
Oct 20.86	11184	$< 5.5 \times 10^{-9}$
20.92	11185	$< 3.7 \times 10^{-9}$
20.99	11186	$< 3.3 \times 10^{-9}$
21.07	11187	$< 3.4 \times 10^{-9}$
21.13	11189	$< 3.5 \times 10^{-9}$
21.20	11190	$< 3.5 \times 10^{-9}$
21.27	11191	$< 3.3 \times 10^{-9}$
21.33	11192	$< 3.2 \times 10^{-9}$
21.39	11193	$< 3.2 \times 10^{-9}$
21.53	11194	$< 3.2 \times 10^{-9}$

emission arises from the shock heating of dense circumstellar material by the nova ejecta. Only systems with a high density in the accretion flow, such as recurrent novae, will therefore generate large X-ray luminosities.

There is little observational evidence to test a relationship between recurrent activity and X-ray emission in optical novae; consequently, a search has been made through Ariel V data for times at which an optical nova was within the 17° field of view of the Rotation Modulation Collimator (Experiment A). Ten orbits of observations in October 1976 coincided with the maximum of nova Vulpeculae which was within the field of view from October 20.83 UT to October 21.53 UT. The optical outburst of this nova was detected by Alcock⁵ at a visual magnitude of 6.5 on October 21.764 UT. Gorynya⁶ reported a photographic magnitude of 8.8 on 20.696 UT which, together with a pre-outburst measurement by Shao⁷ of $m_{\text{phot}}=18.3$, indicated that the nova was near maximum during the Ariel V observations, and hence a likely source of X-ray emission.

No significant X-ray flux was detected and so an upper limit to the ratio of X-ray to optical luminosity of $\sim 10^{-1}$ can be set from these measurements, suggesting that nova Vulpeculae 1976 may be similar to nova Cygni 1975 in this respect.

Table 1 lists the upper limits to the X-ray flux from nova Vulpeculae for each orbit, together with the mid-time of each data integration. The upper limits are uncertain to within a factor of two due to the non-uniform spectral response of the detectors which are sensitive in the energy range 2.94–7.60 keV.

Table 2 is a compilation of the measurements of X-ray emission from optical novae and contains the ratio of X-ray to optical luminosity and the available evidence for recurrent

Table 2 X-ray emission from optical novae

Name	L_x/L_{opt}	Evidence for previous optical activity
A1524-61	$\sim 1.5 \times 10^2$	None reported, probably too faint for plate searches
nova Monocerotis 1975	$\sim 10^3$	Previous outburst, reported by Eachus ⁸
nova Cygni 1975	$< 10^{-4}$	No search reported
nova Vulpeculae 1976	$< 10^{-1}$	No previous activity back to 1896 in Harvard plate collection

optical activity. A search has been made by L. J. Chaisson (personal communication) in the Harvard Plate Collection for previous outbursts from nova Vulpeculae but none have been detected back to 1896, consequently the small amount of data available at present in Table 2 does not conflict with the hypothesis that X-ray emission accompanies recurrent activity in optical novae. The study of optical novae would clearly benefit from more X-ray observations at the period of maximum light.

I am grateful to Dr L. J. Chaisson for communicating the results of the Harvard plate search and to Dr J. L. Culhane for helpful discussions.

Electron-positron flux at the surface of the pulsar in the Crab

LARGE magnetic fields at the surface of neutron stars favour the formation of a condensed phase of electrons and positrons. It is possible to account for the narrow γ -ray line recently observed in the Crab spectrum from this phase with a flux of electrons and positrons at the surface of the neutron star in the Crab consistent with a recent model.

Leventhal, MacCallum and Watts¹ have, with a balloon-borne γ -ray telescope, recently detected a line feature at 400 keV emanating from the Crab nebula. This energy has the correct magnitude of red shift to be due to two-photon electron-positron (e^-e^+) annihilations at the surface of the pulsar in the Crab. About 10^{-3} photons $\text{cm}^{-2} \text{s}^{-1}$ are detected, which if they are emitted isotropically imply that the rate of annihilations at the pulsar is at least 10^{41}s^{-1} . If the annihilations take place in the polar gap region alone, and the photons travel along the magnetic field lines, this number is reduced to about 10^{40}s^{-1} . The most surprising feature of Leventhal *et al.* observations is the width of the line which is determined by the resolution of the detector to be less than 3 keV. One expects the spectrum over which the annihilation photons are distributed to be determined by the transverse momentum of the electrons and positrons in the magnetic field. For a field of 10^{12}G , this may be determined to be about 50 keV. Fields less than 10^{12}G are considered unacceptable at the surface of the pulsar in the Crab.

A possible mechanism to have narrow lines from e^-e^+ annihilation is for the annihilation to be stimulated by annihilation photons. This leads to the amplification of photon density near a particular energy. Stimulated annihilation processes require population inversion. In the present context this means that the electron and positron fluids be nearly degenerate—the density be such that the Fermi energy is much higher than the temperature.

The large magnetic field at the surface of neutron stars favours the condensation of electrons and positrons into rod-shaped droplets. The density in the droplets is high enough to obtain degeneracy.

Following Ruderman's² calculations of the properties of matter in superstrong magnetic fields, Chui³ has variationally estimated the binding energy of an electron-hole droplet in large magnetic fields in a semiconductor. One can equally well use this estimate for an e^-e^+ fluid. The variational estimate of the binding energy is

$$E_b = -13.4 (a_0/\rho_0)^{2/3} e^2/a_0 \quad (1)$$

where a_0 is the Bohr radius and ρ_0 is the cyclotron radius. The

radial extent of the electron or positron wave function transverse to the field

$$r \simeq 1.1 a_0 (\rho_0/a_0)^{2/3} \quad (2)$$

the linear density of the drop along the magnetic field

$$l^{-1} \simeq 1.72 a_0^{-1} (a_0/\rho_0)^{2/3} \quad (3)$$

and the Fermi energy of the one-dimensional fluid is

$$E_F = (h^2/2m)l^{-1} \quad (4)$$

For $B = 10^{12}$ G, one gets $\rho_0 \simeq 4.9 \times 10^{-3} a_0$, $r \simeq 0.15 a_0$, $l \simeq 0.075 a_0$, $E_b \simeq -2.75$ keV, and $E_F \simeq 3.9$ keV. Since the temperature at the surface of the neutron star in the Crab is estimated to be less than 0.5 keV, I concluded that if a steady state with the above parameters is attained, the droplet is indeed degenerate.

I shall next consider whether a steady state can be reached. The electrons and positrons arrange themselves in parallel rods among which there will be a weak residual van der Waal's attraction which may or may not be sufficient to bind them to each other. If they bind, the rods will be spaced at several times $2r_0$ in a droplet; say equal to αr_0 . In each rod, the spontaneous annihilation rate for e^-e^+ pairs is approximately given by

$$\tau_s^{-1} \simeq r_0^2 \rho v \quad (5)$$

where r_0 is the classical electron radius, v is the Fermi velocity and ρ the density. The total number of annihilations per second per unit volume is $r_0^2 \rho^2 v$. For the parameters listed above one estimates this to be $10^{38} \text{ s}^{-1} \text{ cm}^{-3}$.

Suppose there is a flux density of e^-e^+ of $\phi \text{ cm}^{-2} \text{ s}^{-1}$ in a given region at the surface of a pulsar. One can roughly estimate the steady-state radius of the droplets, R by equating the annihilations with the introduction of pairs into the droplets assuming the latter occur uniformly over the surface of the droplet. If $R \gg r$, one may conclude that a steady state is possible, and not otherwise. I estimated that $R \simeq 10^{-38} \phi \alpha^2 \text{ cm}$. For the worst case, $\alpha = 1$, one requires $\phi \gg \phi_0 \simeq 10^{38} \text{ cm}^{-2} \text{ s}^{-1}$ to get $R \gg r$.

In one of the more successful models for radiation mechanisms from pulsars^{4,5}, e^-e^+ positron discharges have a crucial role. A flux density of only 10^{24} s^{-1} is allowed in these models from discharges at the 'near gap'⁵. However, an 'outer gap' has been proposed⁶ which generates photons of high enough energy that pair production on magnetic field lines ensues. A flux $\phi \gg \phi_0$ at the surface of the neutron star in the Crab in a region of the polar cap outside the projection of the 'near gap' is quite consistent with this model. Thus the existence of the e^-e^+ droplets depends on this model. Such a flux also accounts for the total number of e^-e^+ annihilations observed by Leventhal *et al.*¹.

Having examined the conditions and characteristics of stimulated annihilation radiation from the droplets, I found that for the length of the droplet greater than 10^{-4} cm , nonlinear amplification of the photons travelling along the length of the drop occurs. The amplification rate is time dependent and the linewidth depends on the amplification rate and can on the average be much less than 3 keV. I also found that the photons thus emitted can escape the magnetosphere around the pulsar with negligible loss. I will publish the details of these calculations later.

I thank P. W. Anderson, E. I. Blount, Andrew Cheng and M. Ruderman for discussion and encouragement. I also wish

to thank M. Leventhal for discussion of his results before publication.

Pre-biotic molecules in Martian dust clouds

THE search for life on Mars has so far proved disappointing¹. Experiments on the Viking package were designed on the presumption that any microbial life on Mars would be endowed with metabolic processes similar to present-day microorganisms on Earth. Analyses of gases released in soil heating experiments² have provided no evidence for significant abundances of highly complex organic molecules. These data are however, limited to only two landing sites and moreover the compositional studies carried out so far reflect properties of only a relatively thin dust layer on the Martian surface. Dust sucked up into the atmosphere from large areas of the planet's surface would have been witnessed in the 1971 storm, representing a much broader sampling of Martian surface material. Here we propose that a broad absorption feature centred on a wavelength close to 2,200 Å, derived from scattering studies of these dust clouds, may be a signature of highly complex organic or prebiotic molecules.

Recently, the possibility that a primitive life form could evolve in the interstellar medium resulting from the formation and destruction of clumps of inorganic grains coated with organic polymers has been discussed³. The identification of the well-known 2,200-Å interstellar absorption band with electronic transitions in a wide class of organic molecules provides tentative support for this

Fig. 1 Absorption index k of Martian dust (1971 dust storms) from Pang and Ajello⁴.

proposal—at any rate for the occurrence of highly complex organic molecules within grains. Also, a similar feature found by Sakata *et al.*⁴ in the organic matter extracted from a carbonaceous chondrite is suggestive of a dormant proto life form in the nature of interstellar grain clumps.

Pang and Ajello⁵ have recently deduced the wavelength dependence of the absorption index k (complex refractive index $m = n - ik$) of Martian dust from an analysis of the scattered light in the 1971 dust clouds observed by Mariner 9. Such clouds are swept up from a large area of the Martian surface and their composition may thus be more representative than that of the exceedingly small sample studied in the Viking experiments. The absorption index deduced from these data is negligible throughout visible wavelengths but increases in the ultraviolet to show a conspicuous hump at a wavelength close to $\lambda = 2,200 \text{ \AA}$ (Fig. 1). The half-width of this band, $\sim 150 \text{ \AA}$, is similar to that of the interstellar extinction band, and also to the absorption band associated with complex organic molecules of the type discussed by Hoyle and Wickramasinghe³. Although a tentative identification of this band with TiO_2 (anastase) grains has been suggested³, an association with pre-biotic organic molecules securely lodged within clumps of refractory grains is a distinct possibility which cannot be ruled out by the present data. We note that the strength of the interstellar $\lambda = 2,200 \text{ \AA}$ band is incompatible with absorption by TiO_2 grains (assuming solar abundances), whereas $\sim 10\%$ of interstellar C, N, O in the form of pre-biotic molecules may be shown to provide the observed band strength. Similarly, there would seem to be no compelling geological reason for an over-abundance of Ti on the Martian surface. On the contrary, studies of Martian soil have given an upper limit of 1% (ref. 6) by mass to the titanium content, whereas the titanium composition of dust in the 1971 cloud required to explain the data in Fig. 1 is a few percent³. More accurate and extensive spectroscopic studies of Martian dust clouds may well hold vital clues which have a bearing on the question of complex organic molecules and primitive life forms on Mars, as well as their possible connection with a meteoritic and interstellar origin.

Jurassic sea-floor spreading in the eastern Equatorial Atlantic

THE history of sea-floor spreading in the Equatorial Atlantic is poorly known, having been largely inferred from the configuration of fracture zones and the geometry of magnetic lineations in other parts of the Atlantic (Fig. 1). Uncertainties in determining crustal ages at these low latitudes arise partly because of the small amplitudes of the magnetic anomalies and partly because of structural complexities, the separation of South America and Africa involving movements along closely spaced, east-west fracture zones¹⁻³. In this report we describe a series of magnetic anomalies in the eastern Equatorial Atlantic which can be dated using the Vine-Matthews hypothesis⁴ and the time scale of geomagnetic reversals derived by

Larson and Hilde⁵. The age of the anomalies provides an important constraint on the timing of the early rifting phase of the Atlantic off Guinea, Sierra Leone and Liberia.

Three magnetic profiles recorded from RRS Shackleton in 1974-75 are presented in Fig. 2. Also included is a published set of anomalies⁶ observed along a WNW-ESE track at 20°N and a corresponding profile computed for a simple spreading model. At 20°N Hayes and Rabinowitz⁶ identified anomalies M2 (Barremian) to M25 (Oxfordian) and have extended this sequence south of the Cape Verde Islands to the vicinity of a fracture zone at 13°N . A magnetically quiet zone occurs to the east which, in its outer portion at least, seems to have resulted from sea-floor spreading during a long period of constant magnetic polarity that ended in the Lower Oxfordian^{5,6} (Fig. 2). Profile 1 lies 110 km south of Glomar Challenger site 367 where sediments of Oxfordian(?)–Kimmeridgian age have been found resting on basaltic basement⁷. On this line, Upper Jurassic anomalies M19–M24 can be identified, together with anomalies of Lower Cretaceous age. The pattern is displaced 160 km in the left-lateral sense from the lineations south-east of the Cape Verde Islands. Whether the displacement takes place entirely at the 13°N fracture zone or along a series of faults cannot be evaluated from present information. A magnetically quiet region occurs on profile 1 but it is significantly narrower than that observed further north (Fig. 1).

Anomalies along tracks between 11°N and 7°N cannot be correlated with those on profile 1, probably because of structural complications associated with the Guinea⁸ and Sierra Leone⁹ fracture zones. Mesozoic lineations are, however, again identified further south. The sequence is

Fig. 1 Mesozoic magnetic lineations in the Eastern Equatorial Atlantic, numbered according to the reversal time-scale of Larson and Hilde⁵. Anomalies north of 13°N are taken from Hayes and Rabinowitz⁶. The inset map is based on crustal ages given by Pitman and others²⁷ and bathymetry is drawn from charts of Uchupi²⁸. Lines 1–6 are tracks of RRS Shackleton. Magnetic anomalies along profiles 7 and 8 have been made available by the Woods Hole Oceanographic Institution and the United States Geological Survey, respectively. Positions 13 and 366–368 are sites drilled by Glomar Challenger. Ages of oldest sediments recovered are: 13 (Senonian; acoustic basement not reached²⁹), 366 (Maestrichtian; acoustic basement not penetrated⁷), 367 (? Oxfordian to Kimmeridgian; acoustic basement penetrated⁷), 368 (Albian; acoustic basement not reached⁷).

Fig. 2 Correlation of magnetic anomalies. Profiles marked Model and 20°N are taken from Hayes and Rabinowitz⁶. The former profile was calculated using the simple spreading model at the top of the figure. Shaded blocks are normally magnetised. A change in the magnetisation of the basement from 0.007 to 0.0035 electromagnetic units occurs at the position indicated. Anomalies are numbered according to the timescale of Larson and Hilde⁵. Note that a magnetically quiet region immediately west of the continental slope is absent on profile 2, which crosses the Guinea fracture zone.

most complete on profile 3, with the distinctive Kimmeridgian–Oxfordian anomalies M20–M24 clearly defined (Fig. 2). Although of small amplitude, M17 and M18 of Tithonian age can be recognised, in addition to Lower Cretaceous anomalies M11–M15. Correlation with adjacent tracks indicates that the anomalies trend in approximately the same direction as the Liberian continental slope and are displaced about 370 km to the east of those in the central Gambia Basin.

Crustal ages adjacent to the West African margin and in the south-western part of the Sierra Leone Basin are a matter of conjecture since the M-sequence on profile 3 is bounded by magnetically quiet regions, which are open to a number of interpretations^{10,11}. An indication of their nature in this region is provided by their relationship to crustal structure, shown in Fig. 3. The structural section is primarily based on published seismic refraction results¹², although additional gravity and seismic reflection profiles recorded from RRS Shackleton have been taken into account in computing the crustal model presented here. The abrupt transition from the M-sequence to the outer quiet zone coincides with the limit of an area of unusually thick crust, characterised by high seismic velocities (7.0–7.3 km s⁻¹) in its lower parts. The edge of the quiet region therefore seems to be a structural boundary. The composition of the 7.0–7.3 km s⁻¹ material cannot be interpreted unambiguously, but it is probable that it is largely made up of high-grade metamorphic equivalents of the gabbroic 6.2–6.7 km s⁻¹ layer¹². Thus, one explanation of the magnetic smoothness is that it has arisen from a period of crustal reheating during which the basement magnetisation acquired at the ridge crest was destroyed, the crust later becoming remagnetised in a uniform direction. Such a metamorphic episode may have been closely related to the uplift of the Sierra Leone Rise (Fig. 1). The magnetically quiet zone is clearly not restricted, however, to the region with high basement velocities, as it continues for at least a further 90 km to the south-west (km 1,130–1,220, Fig. 3). The outer section of normal oceanic crust is extensive enough to suggest that it was formed during the long post-Aptian period of normal magnetic polarity (Fig. 2), a tentative interpretation which implies that the anomalous crust is no younger than mid-Cretaceous. A magnetic edge effect at the boundary near km 1,130 (Fig. 3) is absent, perhaps because the anomalous crust is magnetised in the same direction as the sea floor to the south-west. At these low latitudes, variations in the intensity of basement magnetisation, resulting from different cooling histories,

are unlikely to be discernible from surface magnetic profiles.

The M-sequence and most of the quiet zone lying adjacent to the continental margin occur in an area of normal crustal thickness for a deep ocean basin. The quiet region starts near the Sierra Leone fracture zone (F.Z., Fig. 3), which is recorded on seismic profiles as an area of complex basement topography, and ends where the Moho dips steeply eastwards, the termination being marked by a positive magnetic anomaly and steep free-air gravity gradient (near km 410, Fig. 3). A similar magnetic signature has been observed on other aseismic continental margins and can be attributed to an edge effect caused by the juxtaposition of weakly magnetised continental crust and strongly magnetic oceanic basement¹³. Its identification in this region and the presence of the Moho at normal oceanic depth under much of the quiet zone suggests that an extensive rift, floored by oceanic crust, was in existence off Sierra Leone and Liberia by Oxfordian (M24) time. The formation of the Sierra Leone Basin is thus related to the opening of the Atlantic further north and, therefore, to the movement of North America from Africa. During the early stages of rifting off Sierra Leone the South Atlantic remained closed, as the oldest oceanic magnetic anomalies south of the equator are of Lower Cretaceous (Valanginian) age¹⁴.

The development of an oceanic rift in the Sierra Leone Basin during the Jurassic appears to be broadly consistent with the history of adjacent parts of West Africa and offers a plausible explanation for intrusive activity and subsidence near the present continental margin during Jurassic–Cretaceous time. In Liberia and Sierra Leone the edge of the West African craton experienced an episode of igneous activity during the early Jurassic, with the intrusion of tholeiitic dykes parallel to the present continental margin and the emplacement of a deep-seated, basic complex around Freetown^{15–19}. The dykes are abundantly developed on land and are known to extend beneath the Liberian shelf, giving rise to linear magnetic anomalies¹⁶. The sharpness of the gravity high and the low amplitude, high frequency magnetic anomalies near km 340 in Fig. 3 probably reflect the continuation of the dyke swarm along the outer part of the Sierra Leone shelf. A tensional stress regime, symptomatic of the initial stages of Atlantic rifting, is thus indicated over a large part of this region during Jurassic time. It is interesting that basic dykes of early Jurassic age have also been reported on the eastern side of the Maranhão Basin in Northern Brazil^{20,21}. On the pre-drift

Fig. 3 Crustal structure along profile 3 in Fig. 1 based on published seismic refraction results¹² and the RRS Shackleton gravity profile. Seismic stations indicated by dotted lines are unreversed; the remainder are reversed profiles; F.Z. is the Sierra Leone fracture zone.

continental reconstruction of Bullard and others²² these intrusions form the southern continuation of the Liberian dyke swarm.

In the coastal region of Liberia the Jurassic igneous activity was followed in the Lower Cretaceous by a period of block faulting, subsidence and rapid sedimentation. Four offshore wells near Monrovia reveal a thick section (up to 1,940 m) of dominantly marine Lower Cretaceous sediments resting on basic volcanics, dated as Jurassic at one location and Lower Cretaceous at a second drilling site^{23,24}. Seismic data (ref. 12 and unpublished RRS Shackleton reflection profiles) suggest that more than 2 km of Mesozoic sediments, probably mostly Cretaceous in age, lie beneath the outer shelf off Sierra Leone. The Senegal margin is known to have subsided at least 4 km during the Cretaceous²⁵. However, in this area the first major Mesozoic transgression seems to have occurred before that in western Liberia, as thick marine limestones of Upper Jurassic age have been encountered in boreholes near Dakar. A somewhat later start to rifting off Sierra Leone and Liberia could account for the absence of a continuation of the Triassic-early Jurassic Senegal evaporites²⁶ south of the Guinea fracture zone.

We thank the officers, crew and scientific party aboard RRS Shackleton, the staff of the Research Vessel Base, Barry, and the National Geophysical and Solar-Terrestrial Data Centre, Boulder, for their assistance in this study. Financial support was provided by the Natural Environment Research Council.

Late Quaternary lake levels in southern Afar and the adjacent Ethiopian Rift

A PERENNIAL problem in using evidence of changing lake levels and river activity to reconstruct Quaternary environments in East Africa stems from our frequent inability to distinguish between effects produced by volcanic and tectonic activity and those related to climatic change. We report here evidence for roughly synchronous changes in lake levels in the volcanically and tectonically active regions of southern Afar and the Ethiopian Rift, which parallel those reported from the Sahel¹, the Nile valley², Kenya³ and Saudi Arabia⁴. Such synchronous changes in lake levels,

allied to independent evidence of moister conditions during phases of high lake levels, are best explained through regional fluctuations in climate.

Lake Besaka is situated at the junction of the Ethiopian Rift and the Afar triangle (Fig. 1), and is bounded to the west and east by pre-Holocene fault scarps which run NNE-SSW, parallel to the regional trend of faults in the Wonji Fault Belt. The northern margin of the lake consists of very fresh, unvegetated aa lava which earlier observers^{5,6} attributed to an eruption in the 1820s. Morphologically fresh cinder cones mark the present southern edge of the lake (Fig. 2). Late Holocene to modern tensional fissures at least 30 m deep and up to 4 m wide extend north through the welded tuffs on the southern flanks of Fantale volcano.

The lithostratigraphic sequence above and below the western fault scarp at Lake Besaka (Fig. 3) shows that the lake attained a level of about 10 m above the January 1974 datum level towards 11,000–15,000 BP (Table 1), shortly after a major eruption of olive-green pumice sand and gravel. Above the scarp the pumice is an airfall deposit that covers a Late Stone Age site with nearly a metre of coarse sand and sporadic gravel. Overlying the green sand is a second Late Stone Age occupation layer with abundant obsidian implements, faunal remains and human burials. Quantitative analysis by X-ray fluorescence of the strontium, yttrium and zirconium content of the green sand above and below the scarp and within the marginal fissure site E3 W (Fig. 3) shows that the trace-element content is identical at all sites, as are the refractive indices of the glass and the mineral composition of the sand. The only differences lie in the sedimentary structures and upward coarsening evident in the green sand below the scarp, which reflect deposition within or resorting by the lake.

Fig. 1 Location map of sampled sites.

Fig. 2 Geomorphic map of Lake Besaka. The sketch map is based on air photographs taken in 1957.

The lake level was high ($\geq +10$ m) for an unknown interval during the late Pleistocene before the deposition of the green sand, and fell sufficiently for Late Stone Age man to move out across the former lake floor down to and perhaps lower than an elevation of +4.5 m.

A fall in level following deposition of the 11,000–11,500 BP shell-bearing diatomites above the green sand is evidenced by dark organic clays that locally contain Late Stone Age flakes. The lake rose again during the Holocene to reach the base of the fault scarp at +10 m, and a second layer of diatomite accumulated above the dark clay towards or shortly after 9,500 BP (Table 1). Before attempting to interpret the changing late Quaternary levels of Lake Besaka, it is pertinent to review evidence from the area as a whole (Fig. 1; Table 1).

K'one caldera complex⁷ lies in the Ethiopian Rift some 30 km WSW of Lake Besaka. Recent gully erosion has revealed a horizontal sequence of alternating dark grey clays and brown tuffaceous loams above the welded tuff and

Table 1 Radiocarbon ages from south-central Ethiopia

Specimen no.	^{14}C age (b.p.)	Site	Material	Comments

†Contaminated by much younger carbonate. Mean of two ages: inner sample: $4,490 \pm 115$; outer sample: $5,010 \pm 110$.

thin overlying pumice airfall deposit lining the floor of a degraded caldera. The upper of the three dark clays contains Late Stone Age artefacts, and the transition from Middle to Late Stone Age assemblages at the base of this clay is dated at $14,670 \pm 200$ BP (Table 1). The regular alternation of horizontal clays and loams from Middle to Late Stone Age time, the moisture-tolerant terrestrial mollusc fauna of the middle dark clay, and the present-day lack of standing water in this locality all imply deposition of the clays in moister conditions than those prevailing there today. If so, then the final interval of clay deposition after $14,670$ BP was a relatively humid one, and it is significant that further south in the Galla Lakes region of the Ethiopian Rift lake levels rose at or soon after $14,400$ BP (ref. 8).

At Aladi Springs, about 150 km north-east of Lake Besaka, *Melanoides tuberculata* shells from a tufa containing Late Stone Age implements have yielded an age of $11,070 \pm 160$ BP, which is similar to that for high lake levels at sites in central Afar⁹, the Awash valley¹⁰ and the Ethiopian Rift⁸. We conclude that the 11,000–11,500 BP high level recorded at Lake Besaka was not a solitary local event but was triggered by a climatic oscillation of regional importance.

Two southern Afar sites some 120 km apart show signs

Fig. 3 Block diagram of late Quaternary deposits west of Lake Besaka (not to scale).

of wetter conditions towards 7,000 BP. Lake Hora near Harar was at least 1 m deeper than now at $6,890 \pm 115$ BP; and a shelly tufa was deposited under permanent water on the flood-plain of a now seasonal stream between Aladi Springs and Erer at $6,670 \pm 110$ BP. Lakes Abhe, Afrera and Asal in central Afar⁹ were also very high at this time, and it may be no coincidence that calcium carbonate was being precipitated at the base of the upper dark clay at K'one some $6,810 \pm 120$ yr BP.

A Late Stone Age site above the western fault scarp at Lake Besaka is dated at $4,785 \pm 120$ BP for undisturbed occupation levels near the surface. Calcium carbonate nodules within the pre-Holocene lake clay beneath the green sand below the scarp have a mean age of $4,750 \pm 160$ BP, suggesting mobilisation of younger carbonate at about this time. A single anomalously young date of $5,700 \pm 110$ BP was obtained on charcoal collected from a late Pleistocene cave-breccia containing Middle Stone Age obsidian points at Porc Epic limestone cave near Dire Dawa.

Shell and carbonate are far from ideal for radiocarbon dating, so that a search for more suitable samples is now under way at Lake Besaka, and geochemical assays of the presently dated samples are in progress. Nevertheless, and despite the equivocal significance of certain of these dates (notably I-7971 and SUA-458) it is worth noting that the central Afar lakes⁹ were high from around 10,000–11,000 BP to around 8,500 BP and again from around 7,500 BP to around 4,000 BP. After an early rise in the level of the lakes of the Ethiopian Rift⁸ towards 14,400 BP, lake levels were very high just after 9,500 BP and again towards 6,500 BP. The present evidence from Lake Besaka, K'one, Aladi Springs, Erer and Lake Hora is entirely consistent with other data from outside Ethiopia^{1–4}, as well as with independent evidence from the Ethiopian Rift and Afar^{8–10}, and indicates wetter-than-present conditions after around 14,500 BP, with notably moist climates towards 11,000–11,500 BP, 9,500 BP, 6,500–7,000 BP and 4,000–5,000 BP. The early Holocene climates in south-central Ethiopia thus show signs of four wet pulses followed by progressive desiccation after 4,000 BP. The late Holocene in Ethiopia was a time when increasing burning and clearing of the land for cultivation in the uplands, and grazing by herds of domesticated cattle, sheep and goats in the drier lowlands would have accentuated the biological pressure exerted by falling water-tables and reduced soil-water content on a vegetation adapted to the moister climates of the early Holocene.

This was part of a continuing investigation of the palaeo-anthropology of south-central Ethiopia, directed by Professor J. Desmond Clark, to whom we extend our thanks. We thank NSF for finance, Macquarie University for leave, Dr W. H. Morton for assistance, Drs D. Brown and

B. Verdcourt for identifying the mollusca, and our Ethiopian colleagues for support.

The geochemical significance of positional isomers of unsaturated acids from an intertidal zone sediment

FATTY acids continue to provide insights into the origins and reactions of organic matter in Recent sediments^{1–4}. As part of a wider baseline study^{1,2} we have isolated the fatty acids from a typical temperate intertidal zone sediment located at the south-west of Corner Inlet, Victoria¹. The acid concentration in this core section is very low (13.4 µg per g sediment) and in contrast to most sediments the mono-unsaturated acids predominate over the saturated acids (Table 1). There are also significant quantities of polyunsaturated acids (Table 2) which have rarely been identified in sediments^{5,6} and there has been no detailed study of the isomers present. The carbon number pattern taken together with the degree of unsaturation and the isomer positions are used in this report to confirm a marine diatom input to the sediment distinguishable from that of other micro-organisms.

The sediment core (13–19 cm deep) was collected 6 m above the low water mark from beneath a bed of *Zostera marina* which stabilised the sediment. Terrestrial plant input is minimal. The sediment was sieved to remove any larger organisms and the total extract was obtained by

Table 1 Concentrations of different acid classes

* Mainly iso and anteiso, some cyclopropyl 17:0, 19:0, trace 10-methyl 16:0. † Only t-16:1, t-18:1 positively identified and quantitated.

KOH-methanol extraction¹. Rigorous precautions were taken to exclude contamination and blank runs were performed. The carboxylic acids were obtained by partitioning the acidified extract into heptane-diethyl ether mixtures. The methyl esters (BF₃–MeOH) were purified on silica gel and 5% AgNO₃ silica gel plates. Small quantities of long chain α,ω-dicarboxylic acids and hydroxylated acids were also present¹.

Gas-liquid chromatography utilised glass SCOT SE30 (60 m × 0.5 mm ID; S.G.E. Australia), and stainless steel capillary BDS (46.7 m × 0.25 mm ID; Perkin Elmer) columns. Compound identification was by co-injection and relative retention time measurements. Hydrogenation in methanol over Adams catalyst confirmed the presence of unsaturated acids.

The sedimentary fatty acid concentrations are high in 16:0 (18%), 16:1ω7, 20:4ω6 and 20:5ω3 and low in C₁₈ components (Table 2). This pattern closely resembles that of many species of marine diatoms^{7–9} and is quite unlike most other algal species^{10,11}. A diatom input is further suggested by the positional isomers of the polyunsaturated acids present.

The three 16:2 isomers commonly found in marine phytoplankton are ω4, ω6 and ω7 but only the isomers (ω4 and ω7) commonly found in marine diatoms^{9,10} are found in the sediment. Jamieson and Reid¹¹ reported only the ω4 and ω6 isomers in their extensive study of macroscopic Rhodophyta, Phaeophyta and Chlorophyta species. Similarly, of the three 16:3 isomers present, only the ω4 is in significant quantity. This is the only isomer reported by Ackman and Tocher¹⁰ for four different diatom species. The virtual absence of the ω3 isomer indicates that Chlorophyceae in particular can make only a small contribution to the sediment.

The low levels of C₁₈ unsaturates also suggest a minor contribution from higher plants or green algae. Of the two 18:3 isomers identified, it is the less abundant ω3 isomer which is common to plants and most algae^{10,11}. The tetra- and penta-unsaturated components isolated, while typical of marine diatoms^{7–10}, are also found in varying amounts in other algae¹¹. The complete absence of 22:6 reflects the small contribution from higher marine organisms.

The abundance of these highly unsaturated molecules in the sediment is unusual as it is generally believed that they are rapidly degraded in a sedimentary environment⁴. Cranwell¹² was unable to detect polyunsaturated acids in a lake sediment despite the fact that the presumed major source of the sediment fatty acids were planktonic organisms which contain large quantities of these acids.

This rapid degradation reflects the aerobic conditions to which the unsaturated acids presumably were exposed¹². In our sediment most of the unsaturated acids will be deposited directly into the sediment when the diatoms die, and hence the acids will largely escape the aerobic conditions at the surface. Preservation is then aided by the anaerobic conditions below the surface ($E_H \approx -120$ mV at the studied depth).

Bacteria are known to contribute branched (iso, anteiso and cyclopropyl) acids to sediments^{2,3} but their contribution to unsaturated acids has been less certain². Our sediment contains a wide range of mono-unsaturated acids and particularly significant levels of vaccenic acid (18:1ω7). Unlike plants and most algae^{9,10} bacteria usually have vaccenic acid and not oleic acid as the major 18:1 isomer¹³. We believe that bacteria contribute most of the 18:1ω7 and a significant proportion of the other mono-unsaturated acids in the sediment. Recent results (to be published) from bacteria isolated from the sediment support this view. Probably the branched unsaturated acids isolated are also derived from bacteria.

Van Vleet and Quinn¹⁴ have recently examined the 16:1 and 18:1 isomers in an estuarine sediment and found 8%

Table 2 Concentration of unsaturated acids

Acid	Percentage of total acids*	Concentration ($\mu\text{g per 100g sediment}$)	Acid	Percentage of total acids	Concentration ($\mu\text{g per 100g sediment}$)

* Data quoted to two decimals is only used to indicate the ratio of minor components. Actual accuracy is about 15% and the values are corrected for the slight loss of unsaturated acids on the capillary columns. † Two unidentified isomers. ‡ Mainly Δ^9 . § Trace $\omega 3$ and $\omega 6$ isomers.

in each case were *trans*. In our sediment the percentage of the *cis* isomer is larger (99% for 16:1, 95% for 18:1) and the proportion of *cis* and *trans* for each positional 16:1 and 18:1 isomer varies significantly. The range of *trans* acids in the sediment seems to parallel the range of the corresponding *cis* isomers but the very low concentrations encountered here have prevented us from obtaining unequivocal identifications. These acids and the change of the *cis-trans* ratio with depth are under study. The other *trans* isomer isolated, t16:1‡, is probably of biological origin. This acid has not previously been reported from a sediment, despite its ubiquity in photosynthetic organisms where it is found localised in the chloroplast phosphatidyl glycerol fraction¹⁴. This acid may prove to be a good marker for a contribution from photosynthetic organisms.

This report shows that a detailed study of the gross fatty acid patterns can be combined with the isomeric forms of these acids to be of value to the environmentalist in relating isolates to probable origin. In our case diatoms and marine bacteria are strongly implicated as the major contributors of organic carbon to this typical, temperate intertidal zone sediment.

Are monkeys logical?

THE monkey's status as a thinker has never been high; yet laboratory investigations testify, nevertheless, to the ability of many species of monkey to learn complex tasks, if not to reason. On this latter point, however, hard evidence is significantly lacking. One reason for this is that it is difficult to devise tests which are both meaningful to non-verbal subjects yet satisfy the stringent requirements of a formal reasoning test such as one adapted from Burt¹ which first gives the subject the following information: "Edith is fairer than Suzanne", "Edith is darker than Lili", and then requires solution of the question, "which is the darkest, Edith, Suzanne or Lili?". Bryant and Trabasso² have devised a simplified method of giving such tests to very young children, and we have adapted this into a non-verbal one for use with monkeys.

In Bryant and Trabasso's study, children were first trained to label five rods presented in four subsets as big or small according to the colour and the subsets in which they were embedded. As displayed, however, no size differences were apparent. Thus, for example, a yellow rod (A) was taught as 'taller than' a red one (B), a red one as 'taller than' a blue one (C), a blue rod was learnt as 'taller than' a green one (D), and a green one as 'taller than' a white one (E). On subsequent tests, children were asked to judge the relative sizes of non-adjacent members of the set, for example red (B) against green (D).

Eight adult squirrel monkeys were tested in an apparatus (a Visconsin General Testing Apparatus) which allowed the monkey to view on any one trial, a tray bearing two cylindrical tin containers of equal size but differing in colour and weight. The experimental design is depicted in Table 1. Each monkey was confronted with four pairs of colour discriminations, learnt serially. For half the subjects the rewarded stimulus was heavier than the non-rewarded one; for the other half it was the lighter one. Weight differences were used to emphasise stimulus differences in the course of preliminary training³. Only two weight values were used throughout the experiment, however; the 'heavy' tin in any pair was filled with lead shot, the 'light' one was empty. Thus, no specific weight could be uniquely identified with stimuli B, C and D.

Monkeys were assigned to different colour pairings and the tray colour was also varied from monkey to monkey in an attempt to eliminate fortuitous colour preferences which might affect the crucial test choices. Each pair was

Table 1 Scheme of training paradigm

Series identification		A	B	B	C	C	D	D	E
Pair		1		2		3		4	
Weight	4 subjects	Light	Heavy	Light	Heavy	Light	Heavy	Light	Heavy
Colour (for example)	4 subjects	Yellow	Blue	Blue	Green	Green	Red	Red	White

learnt in serial order from AB to DE to a criterion of 18/20 trials correct for each pair. Choice of one of the tins was rewarded with a peanut located in one of two foodwells directly underneath the stimuli. To indicate choice and secure the reward, the monkey had to manually displace the appropriate tin from its position over the foodwell. After an error, however, the monkey received no reward; the tray was withdrawn in full view of the subject for 5 s, and a screen was then lowered to permit the experimenter to replace the stimulus unseen and restart testing. The respective positions of the stimuli varied from the left to the right of the tray according to a random sequence.

When subjects had learnt all four pairs they were given a second run through all problems in the same order to the same performance criterion. Several subsequent runs then followed in which the number of training trials given per problem was progressively reduced. Finally, five runs were given of one trial per problem in a random order of presentation. A maximum of 50 trials per day was administered. When each monkey had progressed through all stages of the procedure outlined above, it was given a series of 10 critical trials on the B against D comparison (see Table 1). 'Critical' tests, however, were not administered in any session until the animal first recorded a performance of 22/24 correct in the course of 24 successive encounters of training pairs in a random sequence; not more than two transitive tests were administered per session. All choices were rewarded irrespective of bias during the testing phase. When the B against D tests were complete, subjects were given further tests in similar conditions with the AC, AD, AE, CE and BE combinations in counterbalanced order of presentation (these are regarded as less critical as they include stimuli A and E which can be identified as having been invariably rewarded (E) or invariably non-rewarded (A)). All but one monkey learnt the series; the eighth was erratic and did not meet our stringent training criteria sufficiently often to warrant subsequent testing.

In Table 2 the monkey results are compared with the child data obtained by Bryant and Trabasso for 4-yr-old children. These data clearly show a choice profile consistent with the notion that monkey choices are transitive and accord in virtually every detail with the data reported for children.

Are we to assume, therefore, that monkeys solve such problems by means of deductive inference? Certainly the evidence is consistent with the idea that in order to solve such problems, subjects must coordinate two vital pieces of information—for example that C is heavier than B, and that D is heavier than C. There are alternative ways in

which the problem might be solved, however. Among these⁴, the one which is perhaps the most radically at odds with the coordination model¹ assumes that transitive choices result from single binary decision making.

A set BCD, for example, affords three subsets, BC, CD and BD. If a decision is based exclusively on the interrogation of any one subset, and if we assume (in the absence of information to the contrary) that each subset is interrogated equally often, then it is possible to compute the choice proportions to each of the constituent members of the triad BCD on a given trial. If, therefore, the probability of selecting any one of the subsets as a basis for choice is 0.33 (approximately) we can thus predict an overall choice proportion of 0.33 in the case of C (assuming absolute preference for C over B). D has two reference subsets, CD and BD. In the case of subset CD (making the same assumptions as above) the choice proportion predicted for D will be approximately 33%. In the case of subset BD, however, we need assume no consistent preference for either B or D. On the 33% of all occasions on which these comparisons are made, the subject may select either one equally often. In this case, the overall probability of choosing D would rise by a further 16% (with roughly 16% of all choices going to B). Thus we might predict the approximate choice proportions for all three stimuli in the set BCD as follows: B = 0.17, C = 0.33 and D = 0.50.

In a two-choice situation, of course, where B is presented in conjunction with D, C would have to be 'inferred' as a referent (an assumption in common with the coordination model, some theories of perception⁵, and of transitivity⁶ and a reasonable one given the duplicate relationship of C with B and D). In this instance the choice proportions attributable to C when actually present will now add to the overall proportions for D (as half of them will rule out responses to B, the other half will confirm D directly). Thus the probability values for BD in a two-choice situation will now be B = 0.17, D = 0.83.

In the case of comparisons involving an endpoint value, however, (either A or E), fewer subsets will be at chance levels of choice (taking as a total population all 10 triadic permutations of the 5 term series A, B, C, D and E); thus the projection for the average transitive choice proportion is 0.98. Such predictions seem a remarkably close fit to data already obtained in various experiments reported to date (Table 3).

Apart from fitting predictions to existing data, however, to provide an alternative account to the coordination model, there is an empirical test of the relative strengths of these opposed accounts which is made possible if three

Table 2 Transitive choice data for squirrel monkeys compared with the profile reported by Bryant and Trabasso⁴ for 4-yr-old children.

Monkeys					4-yr-old children (B + T) (Experiment 1)				
	B	C	D	E		B	C	D	E
A	0.98	1.00	1.00	1.00	A	0.96	0.96	0.93	0.98
B	—	0.93	0.90	0.76	B	—	0.92	0.78	0.92
C	—	—	0.89	0.87	C	—	—	0.90	0.94
D	—	—	—	0.97	D	—	—	—	0.91

All choices reported for monkeys are significant on a binomial test ($P < 0.001$). Note especially the B against D comparisons which cannot depend directly on 'end-anchoring' effects.

Table 3 Averaged transitive choice data taken from three separate investigations (choice proportions)

Investigation	Choice proportions to pairs with end points	Proportions to the 'critical' pair (BD)	Overall transitive choice proportion
Bryant and Trabasso ² experiments 1 and 2 (5 groups)	0.96 (0.98)	0.85 (0.83)	0.94 (0.96)
de Boysson-Bardies and O'Regan ⁷ experiments 1 and 2 (2 groups)	0.91 (0.98)	0.82 (0.83)	0.90 (0.96)
This work (1 group)	0.93 (0.98)	0.90 (0.83)	0.92 (0.96)
Average (all investigations)	0.95 (0.98)	0.85 (0.83)	0.93 (0.96)

Values in parentheses are predicted values from a binary choice model (basis of computation outlined in Table 4).

(or more) stimuli, for example B+C+D, are actually presented to the subject for choice following establishment of strong preferences within subsets BC and CD. On the coordination model it is not readily apparent why the actual presentation of the three relevant terms would do other than emphasise further the choice bias in favour of D obtained in the course of two-choice transitivity tests (for example BD). On the binary sampling model, however, a 'reduced' transitive effect is demanded whereas no such predictions are afforded by the coordination theory. We report below a direct test of these positions.

The seven remaining monkeys were presented with 10 triplets derived from all possible triadic combinations of the five stimuli in the original set (A, B, C, D and E). Each session began with 25 trials involving the original training pairs presented in random order. If not more than two errors were recorded, monkeys were then confronted with a three-choice situation where, for another 25 trials per session, each of the 10 triplets was presented in a counterbalanced order. The position of each stimulus on the tray was also counterbalanced. The stimuli were either all 'heavy' or 'light' in accordance with the previous training history of the animal. All choices were rewarded, and the experiment was terminated when subjects made 10 separate choices to each of the 10 triplets presented for test.

Table 4 Profile of choice following triadic presentations

Triads	Choice projection*			Obtained		
ABC	00	33	67	00	31	69
BCD	17	33	50	03	36	61
BDE	17	17	67	16	24	60
CDE	00	33	67	11	24	65
BCE	00	33	67	06	28	66
ABD	00	50	50	00	44	56
ACD	00	33	67	00	30	70
ADE	00	33	67	01	21	78
ABE	00	33	67	00	30	70
ACE	00	33	67	00	26	74
Average distribution	0.03	0.33	0.64	0.04	0.29	0.67

The figures in the left-hand column are predictions based on the assumptions that the subsets are sampled equally often and that preferences are absolute within those subsets presented during original training.

*Basis for predictions in Table 3.

Table 4 shows the overall choice profile in these conditions, and shows how the response distributions for triads are well predicted from a binary (statistical) decision model. By contrast, a coordination model² does not readily lend itself to any quantifiable prediction of a reduced transitive effect. On the contrary, with the relevant choice items in the immediate perceptual field, the 'transitive' choices should, if anything, be all the more pronounced.

Whatever the case for, or against, deductive reasoning which may be fashioned from results such as those reported here, it is clear that some kind of 'inference' necessary to produce the appropriate 'inferred' set or absent referent is used by monkey in tests of transitivity such as those described here. Whether such operations (of 'inference')

provide for the foundations of logical development remains unknown.

Dissolved ATP in the sea and its utilisation by marine bacteria

THE biologically labile fraction of the dissolved organic matter (DOM) in the oceans seems to be a chemically complex solution of a wide variety of compounds derived mainly from the contents of cellular metabolic pools released into the seawater after the death and cell lysis of marine organisms. This fraction is of particular geochemical interest because of its importance in understanding the cycling of organic matter in the marine environment. Because of methodological problems arising from the extremely low concentrations of individual compounds, compound-specific analyses have been limited to only a few components of the DOM, such as amino acids¹, lipids², sugars³, and vitamins⁴. Adenosine-5'-triphosphate (ATP) would be a useful tracer for following the production and fate of labile DOM in seawater as it is a universal component of the cellular metabolic pools of all living organisms. We report here that dissolved ATP (DATP) occurs in seawater in significant concentrations (0.1-0.6 $\mu\text{g l}^{-1}$) and is utilised rapidly by marine bacteria.

Although the particulate ATP content of marine seston (suspended particles) has been used extensively as a sensitive indicator of microbial biomass in oceans and lakes⁵, the presence of DATP in seawater had not been demonstrated conclusively⁶. This has been due, in part, to the absence of a suitably sensitive method, and, in part, to the general assumption that ATP is so rapidly degraded by transphosphorylases and ATPases after cell death as to preclude its presence in the DOM. We considered that the rate of enzymatic breakdown of DATP in the sea might be negligible because extreme dilution of both the enzymes and the substrate occurs after cell disruption.

DATP concentrations in coastal waters of Southern California and British Columbia, Canada were measured using a modification of the method of Hodson *et al.*⁶, which was developed originally for determination of ATP associated with organisms in marine sediments. Seawater samples (50 or 100 ml) were first filtered through 0.2 μm Nuclepore filters to remove ATP associated with organisms and other particles. Filtrates were acidified to 0.6 N with sulphuric acid. A trace amount of $\gamma\text{-}^{32}\text{P}\text{-ATP}$ (less than 1 nCi per sample; 700 Ci mmol⁻¹) was added as an internal standard and the sample was passed through a column of activated charcoal. Adsorbed ATP was then eluted with

5 ml ammoniacal ethanol (ethanol—ammonia—water, 2:2:1 v/v), dried *in vacuo* at 40 °C, and dissolved in 1 ml Tris (tris hydroxymethyl aminomethane) buffer (pH 7.7, 20 mM). Percentage recovery of ATP was determined by radioassaying the concentrates without adding fluor, by Cerenkov Radiation, so that the same sample could be used to determine ATP. ATP was measured by the firefly luminescence method⁴.

It was possible that DATP in seawater samples was an experimental artefact, and that it was introduced into filtrates by cell lysis during vacuum filtration. This was found not to be the case by comparing the filterable ATP with dialysable ATP. Cleaned dialysis bags (molecular weight cut-off 12,000–14,000) were filled with double-distilled water and autoclaved. These dialysis bags were suspended from the Scripps Institution of Oceanography (SIO) pier to a depth of 1 m for 4–24 h. The contents were removed with a sterile syringe and hypodermic needle, and assayed for ATP as above. DATP concentration in the dialysis bags was not appreciably different from that in filtrates ($\Delta P = 5$ cmHg). Another check was made by filtering aliquots of seawater samples using a range of pressure differentials (2.5–37.5 cmHg) and measuring DATP in the filtrates. No increase in DATP resulted with increasing ΔP .

The concentration of DATP in the relatively oligotrophic surface seawaters off the coast of Southern California varied from an average high value of 218 ng l⁻¹ off the SIO pier to an average low value of 65 ng l⁻¹ at a distance of 4 miles seaward from Point Loma, San Diego, California. In the highly eutrophic waters of Saanich Inlet, British Columbia, the DATP concentration averaged 466 ng l⁻¹. The distribution of DATP with depth was measured at a station 16 miles offshore from San Diego in the San Diego Trough (Fig. 1). The DATP concentration in the euphotic zone averaged 110 ng l⁻¹, decreasing to a uniform value of 40 ng l⁻¹ in the aphotic zone down to a depth of 500 m. At this depth, the ATP content of the particles, including the living organisms, was only 4 ng l⁻¹, which is typical of these waters⁴.

Possible sources of the DATP in surface seawater include phytoplankton mortality due to zooplankton grazing and the attendant release of soluble metabolic pools, and the excretion of ATP by plankton. Possible sources of DATP in the deeper parts of the water column are oceanic mixing processes, and the sinking of faecal pellets, clay minerals, and other particles which may contain associated ATP.

Three possible mechanisms of DATP turnover were examined: spontaneous ATP hydrolysis in seawater, enzymatic hydrolysis by extracellular ATPases, and biological uptake and assimilation. ATP was stable in seawater that had been filtered through 0.2 μ m Nuclepore filters to remove all organisms and then autoclaved (15 min at 121 °C) to denature any ATPases; no loss was detectable after 24 h at 21 °C. The stability was not determined over longer periods of time, but previous work has shown that the half life of ATP in artificial seawater at 21 °C is about 8 yr (ref. 7).

Enzymatic hydrolysis of DATP in seawater was examined by filtering seawater samples through 0.2 μ m Nuclepore filters and following the rate of ATP loss at 21 °C; no detectable loss was observed after a 24 h period.

Rapid turnover of DATP occurs when living organisms are not removed from seawater samples. Turnover rates were determined by measuring the assimilation of 2,8-³H-ATP by the natural microbial populations present in the samples. Controls, which received 1% formalin before addition of ³H-ATP, accumulated (adsorbed) ³H at less than 5% of the experimental samples. Using U-¹⁴C-ATP as tracer, it was determined that more than 98% of the ¹⁴C taken up was assimilated, whereas only an insignificant fraction was respired. Turnover rates varied as expected, but were quite rapid in all samples, with rates

Fig. 1 Dissolved ATP concentration as a function of depth from 32°41.6'N; 117°22.7'W in San Diego Trough.

as high as 15.2% h⁻¹ in a sample collected in Saanich Inlet, British Columbia; the range was 0.59–15.2% h⁻¹.

To estimate what part of the ATP uptake was due to bacteria, the seawater samples were first incubated with ³H-ATP and then equal aliquots were filtered on 0.2 μ m and 0.6 μ m Nuclepore filters, and the ATP assimilation by total and 0.6 μ m filterable organisms determined. It has been shown previously that the assimilation of radiolabelled organic compounds from seawater by 0.6 μ m filterable particles can be treated as being of bacterial origin⁴. About 80% of the assimilation of DATP was bacterial; the rest is assumed to be due either to algae and micro-zooplankton; or to bacteria attached to larger particles. We have previously shown that bacteria are responsible for 80–90% of the assimilation of dissolved D-glucose, L-serine, and acetate from seawater⁵.

Twelve isolates of marine bacteria were examined for their ability to assimilate 2,8-³H-ATP. Eleven of these isolates were highly efficient in assimilating DATP. Bacterial growth in the sea is characterised by extreme limitation of carbon and energy sources, individual growth substrates being present at nanomolar concentrations. The presence of a significant concentration of DATP which is rapidly turned over suggests that ATP may be an important carbon and energy source for marine bacteria. Its ubiquitous presence in seawater and the fact that its concentration can be determined with great sensitivity (10⁻¹¹ M), may make the measurement of its flux into marine bacteria a useful indicator of bacterial heterotrophic activity in a given body of seawater.

We thank E. Moussalli for technical assistance. This work was supported by ERDA and IDOE/NSF.

Sex pheromone of the California red scale, *Aonidiella aurantii*

THE California red scale, *Aonidiella aurantii* (Maskell), is the most important citrus pest in Australia, California and the Mediterranean countries. It has been found¹ that red scale females attract males with a sex pheromone, and preliminary studies² have indicated that a branched acetate may be involved. Much interest has been generated in the identification of this pheromone because no other Homopteran sex pheromone has been reported and because the synthetic pheromone has immediate application in replacing the commercial virgin female traps used extensively in monitoring this pest. The sex pheromone reported here consists of two novel components, 3-methyl-6-isopropenyl-9-decen-1-yl acetate (I) and (Z)-3-methyl-6-isopropenyl-3, 9-decadien-1-yl acetate (II). The norsesquiterpene structures represent interesting biosynthetic pathways since they do not merely involve head-to-tail coupling of the isoprenoid units. These compounds also present a synthetic challenge because (I) possesses two asymmetric centers and (II) possesses one asymmetric centre (Fig. 1).

Fig. 1 Components of sex pheromone from California red scale.

Crude pheromone was first obtained from condensates from air that had passed over scale-infested lemons into a dry-ice trap. Steam distillate from the aqueous condensate was extracted with ether-hexane (3:1). An improved system later utilised a Porapak Q trap³ and scale-infested potatoes. A total of approximately 400 million female-day-equivalents (FDE) were collected. An FDE is the amount of pheromone collected from one female each day.

Pentane extracts of the Porapak were concentrated and the residue was chromatographed on a Florisil column (1.5 × 50 cm) eluted with 900 ml of a 0-50% gradient of ethyl ether in Skelly B. The fractions (15 ml) were tested for activity in a greenhouse bioassay⁴, in which test materials on filter paper disks were positioned on a 1.8-m diameter turntable, and red scale males were selectively captured on sticky cards (7.5 × 12.7 cm) placed above each sample. A typical test with Florisil fractions resulted in captures of several hundred males with fractions 14-20 and less than three males with any other fraction.

Active fractions were combined and chromatographed on a 10% AgNO₃-Bio-Sil A (20-44 μm) HPLC column (1 × 100 cm)

eluted with 500 ml each of 10% ether and 20% ether in benzene. Bioassay results showed activity in fractions (15 ml each) 9-14 and 29-38. Each set of active fractions was combined and labelled AI and AII, respectively.

AI and AII were purified further by elution from a Lichrosorb HPLC column (0.2 × 50 cm) with 20 ml 1% ethyl acetate in heptane (0.5 min fractions). All activity was collected during the period 7.5-8.0 min for both samples. Collections from gas-liquid chromatography (GLC) columns showed that the activity was associated with one visible peak in each case, with carbon numbers relative to saturated acetates as follows: 3% OV-101 (AI = 12.25; AII = 12.06); 10% XF-1150 (AI = 13.08; AII = 13.00). The components were purified finally by collection from OV-101 to provide approximately 50 μg of each.

The presence of an acetate moiety was indicated by reaction of AII with LAH to yield an inactive product. Activity was restored at the original GLC retention time on OV-101 by treating the product with acetyl chloride. Mass spectra of AI and AII showed M-60 fragments at 192 and 190 m/e, respectively, possibly corresponding to doubly and triply unsaturated 14-carbon acetates. Hydrogenation produced the same product with an M-60 fragment at 196 m/e from both AI and AII; this was converted to the corresponding hydrocarbon skeleton by saponification, substitution of the hydroxyl group with bromine and reaction with LAH. This hydrocarbon exhibited a molecular ion at 198, a major fragment at 155 (M-43), and typical hydrocarbon fragmentation to the base peak at 57 m/e. Ozonolysis of AI did not yield any GLC visible product, but ozonolysis of AII produced an isolable compound identified as 3-ketobutan-1-yl acetate by GLC and mass spectral comparisons with a standard.

The PMR spectrum of AI (C₆D₆; 100 MHz) was consistent with structure I and has δ values as follows: 5.75 (m), 5.07 (d), 5.02 (d) [H₂C=CH-CH₂-]; 4.82 (s) and 4.76 (s) [R₂C=CH₂]; 4.09 (t) and 1.7 (s) [-CH₂-O-CO-CH₃]; 1.95 (m) [3 allylic H]; 1.49 (s) [CH₃C(R)=]; 1.1-1.6 (m) [9 saturated H]; and 0.77 (d) [-CH-CH₃].

The spectrum of AII (CS₂; 300 MHz) was consistent with structure II and has δ values as follows: 5.71 (m), 4.92 (d), 4.87 (d) [H₂C=CH-CH₂-]; 5.12 (t) [R₂C=CH-CH₂-]; 4.7 (s) and 4.64 (s) [R₂C=CH₂]; 3.95 (t) and 1.92 (s) [-CH₂-CH₂-O-CO-CH₃]; 2.27 (t) [C=C(R)-CH₂-CH₂-]; 1.9-2.1 (m) [5 allylic H]; 1.69 (s) and 1.60 (s) [2 CH₃ C(R)=C]; and 1.39 (m) [2 saturated H].

A 1:1 mixture of E and Z isomers of compound II was prepared from either (S)-(+)-carvone or (R)-(-)-carvone. The former produced the R enantiomer (R:S ratio was 95.5:4.5) and the latter produced the S enantiomer (S:R ratio was 96:4). The geometrical isomers were easily separable on several GLC columns, and were characterised by the chemical shifts (CS₂; 100 MHz) of the 3-methyl proton singlet at 1.69 and 1.60 p.p.m. for the Z and E isomers, respectively. The natural compound AII had GLC retention times identical to the synthetic Z isomer on OV-101 and XF-1150, with no evidence for the E isomer. The proton magnetic resonance spectrum of synthetic II (CS₂; 100 MHz) was similar to that of the natural compound (CS₂; 300 MHz), and mass spectra were identical for AII and II, for their hydrogenated products, and for the hydrocarbon skeletons obtained from each.

Greenhouse flight tests showed that the (R)-Z isomer (25-130 ng on filter paper) is competitive with 25 virgin females, whereas the other isomers are inactive. A typical test (25-ng sample, two replicates for two nights) gave male catches of 531 for the (R)-Z isomer and 15, 17, 18 and 15 for the (R)-E, (S)-Z, (S)-E isomers, and the blank, respectively. Preliminary field tests confirmed the strong attractancy of synthetic II (R-Z) compared with standard virgin female traps (200 females per trap). Field studies will be carried out on all enantiomers of II, as well as with those of I when available.

We thank E. Verwiël, TNO, Delft, The Netherlands for the 300-MHz spectrum, and R. M. Silverstein, Syracuse, New York,

Thermal selection of allozyme polymorphisms in barnacles

Is protein polymorphism adaptive or neutral? Attempts to assess the neutrality theory on the basis of gene frequencies and theoretical population genetics models seem, at least to some authors, to be unsuccessful¹. Possible promising approaches involve the search for direct correlation of isozymes with the environment² and with physiological function³. We have tested the effects of temperature on barnacles, because temperature affects protein structure and function^{4,5,6}, as well as size⁷, and because adult barnacles, following larval settlement, are stationary and directly exposed to local temperature variation. Our results suggest strong temperature selection on allozymic and size variations in the acorn barnacle, *Balanus amphitrite*.

Acorn barnacles, genus *Balanus*, are marine crustaceans, with almost worldwide distribution. Our sampling areas were the open Mediterranean seawater canals of the Haifa Electrical Plant Cooling System, where temperature seems to be the only environmental factor distinguishing the cooler inflowing and warmer outflowing canals (about 12 °C and 9 °C mean difference in summers 1975 and 1976, respectively; see Tables). We compared *B. amphitrite* from the cooler and warmer canals for numbers, size, and for allozyme variation at

11 scorable gene loci in 1975 and at 8 differentiating loci in 1976. To compare equal age populations in the cooler and warmer canals, we immersed 625 cm² plastic plates, 100 cm below water surface, in May and removed them in October. A sample of 260 barnacles—six samples, three from the inflowing and three from the outflowing canals—were taken in three repetitive tests, one in 1975 and two in 1976 (from two different pairs of canals, see Tables). Animals that settled on the plates in each outflow have all passed through the relevant inflow. Soft tissues of whole animals were extracted from the calcareous shells, homogenised, and studied using starch gel electrophoresis⁸ for allozymic variation encoded by the following 11 gene loci: phosphoglucose isomerase (*Pgi*); malic enzyme (*Me*); acetaldehyde oxidase (*Ao*); two loci; *Ao-1* and *Ao-3*; malate dehydrogenase (*Mdh-1*); acid phosphatase (*Acph-1*) and esterases (five loci: *Est-1*, *Est-3*, *Est-4*, *Est-7* and *Est-8*).

The number of barnacles per plate (on both sides of the plate) in the inflowing canals was about 2,400 compared with 510 per plate in the outflowing canals. The average size of an individual in a sample from the inflowing canals was 336 mm² (s.d. 104), compared with 135 mm² (s.d. 47) in the outflowing canal ($n_1 = n_2 = 30$; $t = 9.65$; $P < 0.001$). Out of 11 isozymes tested in 1975, three (*Ao-1*, *Est-1* and *Est-7*) showed no differences between the cooler and warmer canals, and were therefore discarded. The remaining eight showed distinct repetitive trends in the 1975 and 1976 tests. First, the estimates (Table 1) of heterozygosity (h) for individual loci decreased significantly in four loci (*Me*, *Acph-1*, *Est-3* and *Est-4*), most remarkably in *Me*. Mean heterozygosity for all 8 loci (H) in the three tests decreased significantly from 0.110 in the cooler to 0.047 in the warmer canal ($P < 0.001$). Second, distinct statistically significant repetitive trends (Table 2), in allele frequencies were found for chosen alleles in seven out of the eight loci. The following alleles increased in frequency in the warm canal: *Me*^{M+}, *Ao-3*^F, *Mdh-1*^F, *Acph-1*^M, *Est-3*^F, *Est-4*^F and *Est-8*^F; there was a non-significant increase in *Pg*^S. Significant deviations from Hardy-Weinberg expectations due to heterozygote deficiencies were found for *Me* in both the cooler and warmer canals ($\chi^2_{(1)} = 10.04$, $P < 0.01$; $\chi^2_{(1)} = 79.6$, $P < 0.001$, respectively), and for *Est-3* in the warmer canal only ($\chi^2_{(1)} = 97.8$, $P < 0.001$).

To obtain an approximate measure of the favoured allele we assume fitnesses W_1 , W_2 , W_3 for *AA*, *Aa* and *aa*, respectively, where a denotes the favoured allele in the warmer canal, and A all the remaining alleles. The relative fitnesses of *aa* compared with *AA* (W_3/W_1) in the warmer compared with the cooler canal for *Me*, *Acph-1*, *Est-3* and *Est-8*, were 3.6, 2.2, 21.3, and 4.4, respectively. Evidently, strong directional selection is

Electrical responses of *Stomatoca atra* induced by an extract of *Aequorea aequorea*

HYDROMEDUSAE swim by rhythmically contracting the circular swimming muscles located in the subumbrella. When species such as *Stomatoca atra*¹, *Sarsia tubulosa*^{2,3}, *Proboscoidactyla flavicirrata*⁴ and *Euphysa japonica*² are disturbed, either by electrical or mechanical stimulation of the exumbrellar surface, the tentacles contract, swimming stops and a tetanic contraction of the radial muscles causes an infolding of the bell margin (Fig. 1b). This protective response is called crumpling⁵ and is initiated by all-or-nothing potentials in the nerve-free, exumbrellar epithelium^{1–4}. *S. atra*, a predacious hydromedusa, is atypical in that it crumples both when disturbed and when in the proximity of large numbers of hydromedusae of several other species. The latter response is initiated by a stimulating substance stored in the mesogloea of the other medusae⁶. The substance is found in crude extracts of *Aequorea aequorea*, *Halistaura celluaria*, *Phialidium gregarium* and *S. tubulosa*, but not in *S. atra* itself. The crumpling response induced by the extract has been suggested to be a feeding response, trapping prey in the infolded margin⁶. By recording the electrical activity during the crumpling response initiated by extracts of *A. aequorea* I have found that this response is coordinated differently from crumpling initiated by electrical or mechanical stimulation.

Suction electrodes placed on the subumbrellar surface of the animal monitored electrical events associated with swimming or crumpling. A crude extract of the stimulating substance contained in *A. aequorea* was prepared by mincing an intact animal with a scalpel blade and collecting the resulting fluid. To induce crumpling a few drops of the extract were added to a chamber containing a specimen of *S. atra* swimming in 4 ml of seawater at 11 °C, the local

Fig. 1 Silhouettes of *S. atra* drawn from photographs. a, At rest. b, During a crumpling response induced by mechanical agitation (MIC). c, During a crumpling response induced by the extract of *A. aequorea* (SIC).

Fig. 2 Electrical activity recorded from the subumbrella of *S. atra*. a, Potentials recorded during swimming. b, Crumpling potentials induced by the *A. aequorea* extract. c, Recovery of swimming potentials after the medium was replaced by fresh seawater.

temperature of seawater. Drops of seawater added to the specimen instead of the extract served as a control for all experiments and in no case did seawater induce crumpling. Normally *S. atra* swims in bursts, but in the presence of the extract, the tentacles contracted, swimming and the associated electrical activity ceased and crumpling pulses⁴ were recorded from the subumbrella (Fig. 2). If the solution containing the extract was replaced by fresh seawater the crumpling pulses stopped, the radial muscles relaxed and swimming resumed (Fig. 2).

Since normal crumpling is initiated by propagated potentials in the exumbrellar epithelium, it was important to determine if the extract initiated such electrical events. *A. aequorea* extract did not excite the exumbrellar epithelium of either intact animals or excised pieces of bell containing only exumbrellar tissue. Excised pieces of bell were used as a precaution against recording potentials from tissues deeper than the epithelium directly beneath the active electrode³. The exumbrellar epithelium in both intact animals and excised pieces of tissue did conduct propagated potentials when stimulated electrically and conduction velocity between two electrodes was unaffected by the extract.

The extract not only causes a cessation of swimming and an infolding of the margin but also manubrial flexion⁶, a behaviour not observed in the electrically or mechanically induced crumpling response¹ (Fig. 1b, c). Manubrial flexion is called pointing and is caused by the contraction of one or two of the four radial muscles⁷. Isolated manubria, which included a portion of the peduncle, pointed in the presence of the extract. Suction electrodes placed over a radial muscle, in such a preparation, showed that each flexion was associated with a burst of potentials different from crumpling pulses (Fig. 3). Manubrial flexion stopped when the extract was flushed out with fresh seawater.

The extract-initiated behaviour is similar to normal crumpling but there are differences between the two responses which indicate that they are coordinated differently. I shall refer to the electrically or mechanically induced crumpling as MIC and crumpling initiated by the stimulating substance contained in some hydromedusae as SIC. *S. atra* has six described conducting pathways and MIC has been shown to involve the swimming and tentacle pathways, which are neuronal, and the exumbrellar and lamellar pathways, which are non-neuronal¹. The crumpling pulses initiated by the extract and recorded from the subumbrellar surface were similar in amplitude and duration to the pulses recorded during MIC from the same tissue by Mackie¹. Crumpling pulses recorded from the subumbrella during MIC originate in the endodermal lamella^{1,2}, and by analogy, the crumpling pulses recorded from the subumbrella during SIC are also conducted in the non-neuronal lamellar pathway. Further, the similarity in tentacle shortening in MIC and SIC indicates that the

Fig. 3 *a*, Electrical activity from the area of a radial canal in an isolated manubrium (i) before, (ii) during and (iii) after the application of the extracts. *b*, Shows the multiple events associated with the pointing response induced by the extract.

tentacle pathways are used in both behaviours. But MIC and SIIC differ in two aspects. First, SIIC does not utilise the exumbrellar pathway as does MIC, since the extract failed to initiate any potentials in that tissue. Presumably the extract excites crumpling through subumbrellar rather than exumbrellar conducting systems. Second, pointing is activated during SIIC but not during MIC therefore. SIIC involves an additional conducting pathway, called the pointing pathway by Mackie and shown by him to be neuronal¹. There is some evidence that a fourth conducting pathways is involved in SIIC. Pointing cannot occur in MIC since all four radial muscles contract tetanically in both the subumbrella and peduncle. In SIIC however, the radial muscles in the peduncle do not contract tetanically (note the difference in the peduncular extensions in Fig. 1*b* and *c*) and are free to be used for pointing; therefore, two functionally distinct regions of the radial muscles (subumbrellar and peduncular) are postulated. It is possible that the bridge pathway¹, a conducting system of yet unknown function, may play a role in selectively activating these separate portions of the radial muscles.

I thank Dr A. O. D. Willows, University of Washington Friday Harbor Laboratories, for facilities and Dr R. K. Josephson, University of California, for equipment.

Bivalent-cation-stimulated ATPase activity at preformed exocytosis sites in *Paramecium* coincides with membrane-intercalated particle aggregates

TRICHOCYSTS of *Paramecium* cells, although representing morphologically specialised¹ secretory vesicles, obey the general rules for exocytosis. Expulsion can be triggered by artificial increase of the intracellular Ca^{2+} -concentration^{2,3} ($[\text{Ca}^{2+}]_i$), that is, by Ca^{2+} -mediated stimulus-secretion-coupling^{4,5}; the trichocyst and the cell membrane fuse to form a transient exocytosis canal^{6,7} through which the protein-contents⁸ are discharged. Unlike other secretory

granules, however, trichocysts are, long before discharge, closely attached in a regular pattern to the plasmalemma which, at these attachment sites, contains regular arrays of membrane-intercalated particles^{9,10} (MIP) (Fig. 1*a,b*). Many MIP occur also within the tip region of the trichocyst membrane; Fig. 1*c* also shows some non-etchable 'membrane-connecting material' between trichocyst and cell membrane which probably corresponds to electron-dense materials seen on ultrathin sections⁹. 'Central granule patches' would correspond to 'fusion rosettes' described also for other ciliates¹⁰ and actinopods^{11,12}. The sporadic occurrence of similar MIP aggregates at presumable exocytosis sites of endothelial¹³ and neurohypophysis¹⁴ cells might indicate that *Paramecium* cells are capable of maintaining an otherwise rather ephemeral situation, that is, the stage of membrane-to-membrane attachment preceding membrane fusion. The requirement of energy¹⁵ and Ca^{2+} (refs 4, 5) and the presumable involvement of bivalent-cation-stimulated ATPase activity¹⁶ in the course of exocytosis led us to search for a functional correlate of the specialised structures observed at exocytosis sites.

Paramecium aurelia K 401, was cultivated monoxenically (*Enterobacter agglomerans*) in a standardised Difco medium. For cytochemistry, conducted at 20 °C, cells were washed three times with a ~300-times excess of 10mM Tris-HCl pH 7.0. Washed cells (~ 2×10^4 per 0.2 ml) were fixed in suspension for 60 s with doubly distilled 2.5% glutaraldehyde in 0.1 M cacodylate buffer pH 7.0 and diluted 1:10 with buffer for 14 min. This method was developed to overcome the marked sensitivity of ATPases to fixation and the discharge of trichocysts by too low fixative concentrations¹⁷. After washing (3×5 min) in 10 ml 0.1 M Tris-maleate buffer pH 7.0 cells were incubated for 1 h in the same buffer (eventually at pH 5 or 9) with the following additives: 2.4 mM Pb^{2+} as a capture ion, 5 mM substrates (ATP as Tris salt), 5 mM bivalent and/or 20 mM monovalent cations (chlorides); inhibitors (5 mM) were added also to the last wash before incubation. All chemicals were of the highest purity available and dissolved immediately before incubation. After three washes cells were osmicated (1% OsO_4 in cacodylate buffer pH 7.0, 1 h) (except cells for X-ray microanalysis), dehydrated in acetone and embedded in Durcupan ACM (Fluka). Uncontrasted silver sections were examined in a JEM 100C electron microscope (100 kV). $[\text{K}^+, \text{Na}^+, \text{Ca}^{2+}, \text{Mg}^{2+}]_o$ were determined by atomic absorption photometry (Beckman, model 1248), flame photometry (Instrumentation Lab. model IL 343) and colorimetry in spectral photometers.

Reaction product (RP) was found around the sites where trichocysts are attached to the plasmalemma (Fig. 2) in the following conditions (pH 7): with $\text{Pb}^{2+} + \text{ATP} + \text{Ca}^{2+}$ or Ba^{2+} ; some, but apparently less, RP was also formed with Mg^{2+} . Addition of Mg^{2+} or Na^+ and/or K^+ did not change the reaction obtained with Ca^{2+} . Similarly RP was formed (although independent from the addition of mono- or bivalent cations) with *p*-nitrophenylphosphate, acetylphosphate, Na-AMP and less with Na- β -glycerophosphate as substrates. RP formation was always independent from osmication or section staining. RP was absent at pH 5 and moderate at pH 9 in conditions yielding strong RP at pH 7.

In the following controls no RP was formed (pH 7): omission of Pb^{2+} or chelation by a fourfold excess of 1,2-dihydroxybenzene-disulphonic-(3,5)Na₂-salt; omission of appropriate substrates; omission of bivalent cations in presence of Tris-ATP; with Na₂-ADP ($\pm \text{Ca}^{2+}$), Na₂-GTP ($\pm \text{Ca}^{2+}$), adenylyl imidodiphosphate (a substrate for the cytochemical assay of adenylate cyclase¹⁸), 3',5'-cyclic AMP or its dibutyl derivative as tentative substrates; after heat exposure during fixation (5 min, 80 °C). Maintaining the original fixative concentration also results in lack of RP. When cells were fixed, soaked in phosphate

Fig. 1 Freeze-cleave replicas obtained with a Balzers BAF 300 (turbomolecular pump; 10^{-6} mbar; 2 min etching at -100°C ; Pt- and C-evaporation by electron beam evaporators). Shadowing direction is from bottom to top. ($\times 72,000$.) a, Cytoplasmic half of the plasmalemma at a trichocyst attachment site; a, 300-nm large double ring⁶ of MIP; b, intermediate MIP; c, 'central granule patch' of MIP⁶ equivalent to 'fusion rosette'¹⁰. b, Outer half of the plasmalemma

of a trichocyst attachment site; explanations for a, c as in Fig. 1a. On this fracture plane the 'ring' is represented by pits instead of MIP, whereas about 10 'rosette' MIP (c) become better visible on this fracture plane. c, Inner half of a trichocyst membrane; note 'annuli'²⁵ of MIP (bracket); corresponding to 'e-type structures' in ref. 6, followed by impressions from the microtubule collar⁶ in the lower portion and non-etchable 'membrane-connecting material' (arrow) between the trichocyst proper and the plasmalemma. For comments on possible structural equivalents of ATPase activity see text.

buffer pH 7 and then in 2.4 mM Pb^{2+} , electron-dense deposits were scattered randomly. Sr^{2+} at pH 9 with subsequent substitution by Pb^{2+} , a method designed for K^{+} , Na^{+} -ATPase¹⁹, gave only spurious RP with various substrate-cation combinations, which resulted in RP formation under 'standard conditions' at pH 7.

At pH 7 media containing Pb^{2+} + Tris-ATP + Ca^{2+} or Pb^{2+} + *p*-nitrophenylphosphate were used with various inhibitors: ouabain for Mg^{2+} -dependent Na^{+} , K^{+} -stimulated 'transport' ATPase^{20,21}, L-tetramisole for alkaline phosphatase²², and atractyloside for transmembrane nucleotide transport²³. These inhibitors all failed to reduce RP formation. Considerable blockage was obtained with Salycarn or *N*-ethylmaleimide which both inhibit various ATPases^{20,23} by interaction with SH-groups.

The ionic milieu can be characterised as follows: $[\text{K}^{+}]$, $[\text{Na}^{+}]$, $[\text{Ca}^{2+}]$, $[\text{Mg}^{2+}]$ were constantly around 1.8, 0.4, 0.17 and 0.17 mM respectively in the culture medium, 0.05, 0.2, 0.05 and 0.04 before glutaraldehyde fixation and 0.04, 0.04, 0.04 and 0.06 during incubation (without salts added). In living paramecia $[\text{K}^{+}]$ ≈ 20 mM (ref. 24), whereas $[\text{Ca}^{2+}]$ probably equilibrates around 0.03–0.05 mM (ref. 25) for our low $[\text{Ca}^{2+}]$ values. Assuming that permeability changes due to glutaraldehyde fixation were similar to those in other cells²⁶, we expect from extrapolation a maximum of $[\text{K}^{+}]$ < 10 mM and $[\text{Ca}^{2+}]$ ≈ 0.04 mM; if the membrane potential generated by high $[\text{K}^{+}]$ and $[\text{Ca}^{2+}]$ in paramecia²⁴, were to break down in response to the insult of chemical fixation, $[\text{K}^{+}]$ and $[\text{Ca}^{2+}]$ could be around 0.04 mM at the sites of RP formation (unless when added in excess). In conclusion, with the possible exception of K^{+} , the concentration of the relevant cations can be assumed to be < 0.1 mM, if no salts were added.

Fig. 2 Cytochemical demonstration of ATPase activity obtained with 5 mM Ca^{2+} + 5 mM Tris-ATP + 2.4 mM Pb^{2+} , pH 7, in conditions specified in the text. This 'grazing' section contains several attachment sites of trichocysts (1–6) in a regular pattern (compare with ref. 6). Only where the section contains uppermost tip regions—with structures represented in Fig. 1—reaction product (RP) is deposited. (1–6) Designate a sequence proceeding from the outside to the inside; (1, 2, 6) are unreactive because the sectioning level is still too high (1, 2) or too low (6). On positive sites RP fills the space delineated by its surrounding membranes (see text and ref. 6). Inset: Longitudinal section through a trichocyst; outlines are marked by arrows; RP only in tip region. Unstained sections ($\times 31,500$).

To determine whether bivalent cations (5 mM) are truly stimulative we analysed whether Pb^{2+} is the true capture ion in our experiments, since the presence of bivalent cations during glutaraldehyde fixation also results in formation of RP-like deposits on some biomembranes²⁷, including Ca^{2+} -binding sites of paramecia^{3,28,29}. Since X-ray microanalysis revealed the simultaneous presence of P and Ca in such deposits, rapid redistribution of intracellular ATP occurring on fixation²⁸ could lead to cleavage and PO_4^{3-} -capturing by bivalent cations at sites of persisting ATPase activity^{3,27,28}, even if these cations were not stimulative. But, X-ray microanalysis of RP formed with Pb^{2+} + Tris-ATP + bivalent cations revealed the selective enrichment of P and Pb only (Fig. 3). Hence, Ca^{2+} , Ba^{2+} and (to a lesser degree) Mg^{2+} are truly stimulative and Na^{+} , K^{+} non-stimulative ions.

The hydrolysis of various orthophosphate substrates in the absence of additional ions (for K^{+} see above) might be due to a phosphatase which splits phosphorylated intermediates generated by various transport ATPases^{20,21}, including Ca^{2+} -, Mg^{2+} -ATPases^{30,31}. Thus the RP at attachment zones of trichocysts to the plasmalemma probably represents an ATPase stimulated by bivalent cations—in physiological conditions most probably a Ca^{2+} -(transport)-ATPase.

Various transport ATPases, including Ca^{2+} -ATPase³² are membrane-integrated oligomeric proteins which would show up in freeze-cleaved membranes as MIP of the usual size range³³. Absence of RP from potential attachment sites (unpublished observations) which contain only 'rings' of MIP if not occupied by trichocysts^{2,34} points mainly towards 'central granule patches' (fusion rosettes) and possibly 'membrane-connecting material' and/or 'annuli' as

Fig. 3 Energy spectrogram obtained from reaction product, specified in Fig. 2, by X-ray microanalysis using an analytical electron microscope JEM 100C (60 kV) in the scanning transmission mode and combined with an eucentric goniometer stage (40°), a Kevex detector and a Link spectrometer unit, system 290. Experimental conditions were as before^{3,30} but C-coated nylon-grids (Touzart-Matignon) were used to mount ~1000-Å thick, non-osmicated, unstained sections. Note the occurrence of Pb-lines Ma (2.342 keV), La (10.550), Lβ₁ (12.612) and of P-Kα₁ (2.013), while Ca-Kα (3.690) is absent. Si-Kα (1.739 keV) is an artefact.

candidates for the structural equivalent(s) of bivalent-cations-stimulated ATPase. Since RP might diffuse within the small cleft between apposed membranes (plasmalemma, trichocyst and alveolar membrane, see ref. 6), further investigations have to envisage a discrimination among these possible candidates.

Several possibilities have to be considered to explain how Ca²⁺ and ATP could intervene in the final steps of exocytosis (see also ref. 16). The local restriction of RP indicates a mechanism involving local [Ca²⁺]-regulation at exocytosis sites. This could entail (1) regulation of membrane repulsion or attraction depending on charge screening, or (2) conformational changes of the 'rosette' MIP or of 'membrane connecting material' reminding the postulated mechanocomplex¹⁰ and the actomyosin-like fibrillar materials occurring at exocytosis sites¹⁵; furthermore (3) Ca²⁺-dependent regulation of lipid phase transitions³⁵ and intramembraneous segregation phenomena¹⁰ could be involved in the local MIP clustering described.

Trichocyst discharge is a very effective, specialised form of exocytosis, but the structural-functional correlations involved could clarify the final steps of exocytosis in other systems.

We thank Mrs Alice T. Orque for technical assistance, Professor H. Bengner and Dr F. Tiefenbrunner for providing laboratory facilities, and the 'Österreichische Forschungsfonds' for financial support.

Transition probability and the origin of variation in the cell cycle

It is well established that the cell cycle times of cells cultured *in vitro* are highly variable although the origin of this variability has remained unclear^{1,2}. A number of theories have been advanced to explain the variation in cell cycle times although none of them give entirely satisfactory fit to the experimental data³. Any proposal as to the origin of this variability must take account of the observation that most of the variability occurs in the G₁ phase of the cell cycle and that it is the length and variability of this phase which is the major determinant of the length and variability of cell cycle times within a cell population¹. A new model of the cell cycle has been proposed independently by two groups that suggests that variability in the G₁ phase of the cell cycle arises as a result of a probabilistic transition occurring within G₁ (refs 3, 4). Using time-lapse cine-photography I have examined the possible role of a number of other factors which might determine this variability and have come to the conclusion that the observed variation in cell cycle times *in vitro* is qualitatively and quantitatively in accord with variation predicted by the transition probability model of the cell cycle⁴.

The transition probability model divides the cell cycle into two parts—the B phase (containing S, G₂, M and part of G₁) where the cells are proceeding towards division, and the A state (contained in G₁) where the cells are awaiting a random triggering event before proceeding. A cell may remain in the A state for any length of time, but in steady-state conditions the probability (the transition probability) of a cell leaving the A state and entering the B phase in any unit of time is constant. In a population of cells the shortest intermitotic time is shown by a cell that leaves the A state immediately it enters. Intermitotic times greater

Fig. 1 Growth curve of Swiss 3T3 cells. The cells were plated in Dulbecco's modified Eagle's medium containing 10% foetal calf serum. The cultures were filmed using a 4-min interval and cell counts made from projections of individual frames of the film. The saturation density of these cells is about 5×10^4 cells cm^{-2} .

than this minimum (equal to the duration of B phase, T_B) should be exponentially distributed in a population of cells with identical T_B values and identical transition probability. A graph of the logarithm of the percentage of undivided cells (α_t) against time (the α curve) would show two

components, since the value of α_t will be 100% for times up to T_B and then decay exponentially. In practice the α curves often exhibit some initial curvature that has been ascribed to variation of T_B within a cell population⁴. But, the values of T_B in sibling cells are apparently very similar so that the distribution of differences of intermitotic times of sister cells (the β plot) is also exponential and parallel to the exponential tail of the α curve^{5,6}.

Heterogeneity of cell cycle times approximating to an exponential frequency distribution may be generated in ways other than assuming a random transition. Since most of the observations to date have been on uncloned cell populations, the observed variability could arise from pooling data from cells with differing constitution. To investigate this possibility the behaviour of single clones of the established Swiss 3T3 mouse fibroblast cell line was observed. Cells were plated at low density and filmed until the culture reached confluence (Fig. 1), and α and β curves were constructed generation by generation for eight separate clones for up to six generations (Fig. 2). Subsequent generations were not monitored because cultures were no longer in a steady state over the period of a generation and the cells were increasingly hard to follow so no further data was collected. The α and β curves reveal two types of clonal behaviour. Most of the clones (six of eight) behaved like the clone (clone 5) illustrated in Fig. 2a. The first four generations of this clone were pooled to provide enough data for α and β curves; it made little difference if the early generations were pooled within or between clones (not shown). After some initial curvature the α curves became exponential and closely parallel to the β curve providing evidence that the variation in cell cycle times is not due to clonal heterogeneity. For this clone the minimum value of T_B was 11.6 h in the first four generations, 13 h by the fifth and 14.3 h by the sixth. Similar increases in the value of T_B with successive generations were noted for all the clones examined although T_B varied

Fig. 2 Semilogarithmic plot (open symbols) of the % of cells (α_t) undivided against age (t) for a clone in the experiment shown in Fig. 1. Also shown (closed symbols) are plots of the % of sibling pairs (β_t) with a difference of intermitotic times $> t$. *a*, $\circ$, $\bullet$, Pooled first four generations; $\triangle$, $\blacktriangle$, fifth generation; $\square$, $\blacksquare$, sixth generation (clone 5). *b*, α plots, β plots of the pooled first four generations of another clone (clone 3) from the experiment shown in Fig. 1. $\square$, $\triangle$, Descendants of the two progeny of the first division. The β curves of these two subclones were identical (not shown) and have been pooled for clarity. *c*, As (*b*) but for the fifth generation. The β curve is pooled from both subclones.

Fig. 3 α and β plots of primary mouse fibroblast (MEF) and primary chicken fibroblasts (CEF). Mouse embryo cells were prepared from whole embryos of Tylers original mice. Cells were plated at 2×10^5 per 5-cm dish in Dulbecco's modified Eagle's medium containing 10% foetal calf serum. Chicken fibroblasts were prepared from 10-d embryos of C/O brown leghorn chicks. Cells were plated at 4×10^5 per 5-cm dish in Dulbecco's modified Eagle's medium supplemented with 10% Tryptose phosphate broth, 1% foetal calf serum and 1% heat-inactivated chicken serum. Both cultures were filmed using a 4-min interval. *a*, α and β curves for MEF. Intermittent times were collected from the progeny of several different cells; $\bullet$, pooled data excluding the three clones shown separately; $\circ$, corresponding β curve. Δ , α Curve from pooled data of three clones in the MEF population; $\triangle$, corresponding β curve for pooled data of three clones. *b*, *c*, α Curves (closed symbols) and β curves (open symbols) for the progeny of two separate CEF cells. In (*b*) the deviation of the points from the drawn α curves is probably due to extensive T_B heterogeneity within a subfraction of the population. Nevertheless, the intermitotic times of 60% of the cells lie on the drawn α curve but the β curve derived from all the cells of the clone is linear.

between the clones and between the generations. Nonetheless, a major cause of the lengthened cell cycle in later generations is the decreased value of the transition probability (estimated from the slope of the β plots).

The other type of clonal behaviour (two out of eight clones) is illustrated in Fig. 2*b* and *c*. In these cases the descendants of the daughters of the first division behave as separate clones differing mainly in the length of T_B . As a consequence the α curves are parallel to each other and the β curves superimposable, this behaviour persists until at least the fifth generation. After this the lifespans of the sixth generation subclones no longer overlapped and the transition probability in the two subclones was different so the T_B difference could not be calculated (not shown). The results from clones of this type show that T_B may (at least in part) be heritable and persists over several generations. This generation of T_B heterogeneity within a clone may be the source of T_B variation within a cell population. Results from the Swiss 3T3 cell line do not support the idea that the apparent exponential component of the variability in cell cycle times within a population arises from clonal heterogeneity as this variability arises even within clones.

It might be argued that karyotypic instability in established cell lines accounts for the variation in cell cycle times even within a cell clone. This possibility has been explored by examining the behaviour of primary cultures of mouse and chicken fibroblasts which are presumably isogenic and diploid. The behaviour of mouse embryo fibroblasts (MEF) is depicted in Fig. 3*a*. The α curve for the pooled data from many different cells (excluding three clones, see below) is sigmoid indicating that a significant fraction of the population did not divide. Nevertheless, a β plot from the same cells is exponential as non-dividing

cells had non-dividing sisters thus giving no value for the difference in intermitotic times. The descendants of some cells could be followed for a number of generations, data from three clones were pooled and α and β plots shown in Fig. 3*a*. The β curve is exponential and parallel to the exponential tail of the α curve. Furthermore, the β curve of the clones is superimposable on the β curve of the pooled data from all the cells which excluded these clones, indicating that the clones are not an unrepresentative fraction of the viable cells. Similar experiments with primary chick fibroblasts (CEF) are illustrated in Fig. 3*b* and *c*. There was considerable clonal heterogeneity in the CEF population so the data could not be pooled. Results from two clones (Fig. 3*b* and *c*) show differences in T_B as well as transition probability, in both cases exponential β curves were obtained.

The α curves shown in this paper rarely extend below the 5% level of undivided cells. This is due to the limited number of cells that can be analysed in a single generation of a single clone. Pooled data from many generations of BALB/c3T3 cells transformed with SV40 virus extended these α plots down to the 0.3% undivided level and the β curve down to the 1% level. The β curve was exponential and parallel to the exponential tail of the α curve⁶.

It could be argued that the exponential kinetics observed is due to escape from some block unwittingly imposed by the conditions of *in vitro* culture. This seems unlikely as free-living organisms such as *Euglena* also have exponentially distributed cell cycle times⁷ as do *Escherichia coli* with cycle times as short as 30 min which are highly unlikely to be blocked (L. Martin, personal communication). Furthermore, the shape of frequency of labelled mitosis curves obtained *in vivo* may be accurately predicted from transition probability theory^{3,4,8-10}, which suggests that cells

in vivo may undergo a similar type of random transition to that observed *in vitro*.

The results in this paper demonstrate that the variability in cell cycle times *in vitro* is not entirely due to pooling data from many cells with different pedigrees nor does it arise from an artefact of using cell lines. These results, together with the fact that the β curves are exponential (which is necessary and a sufficient condition for the existence of a random transition in the cell cycle (R. S. and J. A. Smith, unpublished)), support the idea that the variation in cell cycle times *in vitro* is due in part to a random transition in the cell cycle and that transition probability is a key function that regulates cell proliferation.

I thank Peter Riddle and Diane Brown for filming the cultures, Jenny Beaman for preparing the CEFs and the staff of the cell production unit for preparing the MEFs.

Hybrid cell lines with T-cell characteristics

THE hybridisation of established cell lines with differentiated cells provides a useful strategy for the production of cell lines having differentiated properties and unlimited growth potential. Clones of these hybrids could be particularly useful in the dissection of cellular interactions of the immune system, a network involving numerous specific cell types which display characteristic ensembles of surface and internal markers. We describe, here, the production and partial characterisation of hybrid cell lines with surface antigens characteristic of T lymphocytes.

Köhler and Milstein^{1,2} have shown that the fusion of mouse myeloma cells cultivated *in vitro*, with spleen cells from immunised mice, gives rise to B-cell hybrid cell lines which secrete monoclonal immunoglobulins with antibody activity to the immunising antigen. Although 30–40% of the spleen cells used for fusion were T cells, none of the hybrids expressed the Thy-1 surface antigen, a characteristic marker for mouse T cells. Without expression of this (or some other) T-cell marker, it is difficult to determine in retrospect whether the non-producing hybrids were T cells-myeloma fusion products in which Thy-1 is repressed.³

In contrast with results from the myeloma fusion studies, we found that fusion of spleen cells with a mouse T-lymphoma cell line (BW 5147) gives rise to hybrid cell lines which express T-cell and not B-cell markers. Hybrid populations were obtained by fusing spleen cells from (BALB/c×SJL)_F₁ mice with HAT-sensitive BW 5147-AzG^R, Ou^R cells (kindly provided by Dr Robert Hyman). The BW 5147 cells were HGPRTase negative and resistant to 1×10^{-3} M ouabain. Spleen donors were immunised by intraperitoneal injection of 100 µg of DNP-KLH on alum with 2×10^7 *Bordetella pertussis*, and boosted 3 months later by intravenous injection of 20 µg of DNP-KLH. Cells were harvested from the spleens 4 days later. Hybrids were also obtained by fusing BW 5147 with spleen cells from non-immunised CBA and AKR donors which had been stimu-

lated for 4 or 5 d in mixed lymphocyte cultures (MLC) by irradiated allogeneic spleen cells.

For the fusion, a mixture of 10^8 spleen or MLC-derived cells and 10^7 BW 5147 cells in Dulbecco's Modified Eagles medium plus 10% foetal calf serum (DME-FCS) was pelleted at 400g. The medium was removed and fusion initiated by the gradual addition of 2 ml of 50% (w/w) polyethylene glycol (PEG) 1,000 or 1,500 in serum-free DME. After 2 min at 37 °C, the suspension was then gradually diluted to 50 ml (over the course of 10 min) with serum-free DME and then pelleted by centrifugation⁴.

The pelleted cells were next resuspended and cultured in 0.2- or 2-ml volumes at $1-2 \times 10^6$ cells ml⁻¹ in selective medium (DME-FCS, 100 µM hypoxanthine, 10 µM aminopterin, 30 µM thymidine and 3.3×10^{-4} ouabain). Preliminary experiments have shown that neither spleen cells nor BW 5147 cells survive for longer than a few days in this medium; therefore, after 14 d, selective medium was removed and replaced with DME-FCS. All populations surviving after 2 weeks were presumed to be hybrids since survival requires that the gene for HGPRTase from the spleen cell parent and the (genetic) information for continuous growth from the lymphoma parent both be present in each cell.

In later experiments, cell numbers per well were adjusted to allow one or a few hybrid clones to be seeded. Hybrid populations were transferred when adequate growth was observed. Clonal populations were obtained either by limiting dilution in 0.25-ml wells or by soft agar cloning. Only the (BALB/c×SJL)_F₁ hybrid populations were cloned at the time of this report.

The putative hybrids were analysed for DNA content per cell using flow micro fluorometry in a fluorescence activated cell sorter (FACS-II, Becton-Dickinson Electronics Laboratory, Mountain View, California) after fluorescent straining of the DNA with propidium iodide in hypotonic (0.1%) sodium citrate⁵. Approximately 40 hybrid populations were tested within the first 2 weeks after hybridisation. All had G₁ DNA contents which were about the sum of the DNA contents of spleen cell (diploid mouse) and the near tetraploid lymphoma used for hybridisation.

The expression of both parental Thy-1 alleles on 29/39 hybrid cell populations (and clones) obtained from hybridisation of Thy-1 differing cells demonstrates directly that the hybrids arose from fusion of normal spleen cells and the BW 5147 lymphoma (see Table 1). Specificity of typing was confirmed by quantitatively absorbing the anti Thy-1.2 with hybrid cells and then testing the absorbed antiserum on normal thymocytes to demonstrate removal of anti Thy-1.2 activity. The demonstration that hybrids of BW 5147 with a Thy-1.1 carrying strain, AKR, express only Thy-1.1 rules out expression of a cryptic Thy-1.2 allele by the hybrids (Table 1).

Identification of the splenic lymphocyte subpopulation which fused with BW 5147 to give rise to hybrids expressing both parental Thy-1 alleles is difficult in retrospect; however the increased frequency of such hybrids obtained by fusion of MLC cells, which are nearly all T cells, suggests that the Thy-1.1, 1.2 hybrids are probably derived from fusions of normal T cells with the lymphoma (Table 1). Whether the fusions which gave rise to hybrids expressing only the BW 5147 Thy-1.1 allele were also T cell-lymphoma fusions may become clear as the hybrids are tested for more T-cell markers. Interestingly, the spleen cell hybridisation gave rise to two clones which express neither parental Thy-1 allele, that is in which the BW 5147 Thy-1.1 is lost or repressed.

Preliminary tests for Ly 1,2,3, and Ia markers on the hybrids are consistent with hybrids being derived from fusions of normal T cells and lymphoma cells. The BW 5147 lymphoma comes from a strain which carries

Table 1 Expression of Thy-1 antigens on hybrid cells

Experiment	Hybridisation	Parental populations	Number of hybrid populations expressing Thy-1 alleles*			
			1.1+1.2	1.1	1.2	—
921	AKR T Lymphoma BW 5147 (Thy-1.1)	× (BALB/c × SJL)F ₁ Spleen (Thy-1.2)	18	7	0	2
C.2	AKR T Lymphoma BW 5147 (Thy-1.1)	× CBA Spleen MLC† (Thy-1.2)	11	1	0	0
A.2	AKR T Lymphoma BW 5147 (Thy-1.1)	× AKR Spleen MLC (Thy-1.1)	0	13	0	0
Kohler and Milstein ⁴	BALB/c Myeloma MOPC 21 (X63) (Thy-1 negative)	× BALB/c Spleen (Thy-1.2)	0	0	0	>10

*Populations from experiment 921 are individual clones, populations from experiments C.2 and A.2 are isolates from different fusion hybrids and may contain one or more clones. Thy-1 phenotype was determined by direct cytotoxicity using congenic anti-Thy 1 antisera (experiment 921) and non-congenic antisera (experiments C.2 and A.2). Thy-1 phenotype of several clones in experiment 921 was confirmed by quantitative absorption studies.

†Cells from a 5-d mixed lymphocyte culture (MLC) of spleen cells stimulated with irradiated allogenic cells. Nearly all surviving cells in this culture are T cells from the responder spleen.

Ly-1.2 and Ly-2.1; however it expresses neither of these characteristic T-cell markers. T cells from (BALB/c × SJL)F₁ mice carry Ly-1.2 and Ly-2.2 determinants. Some of the clones derived from the (BALB/c × SJL)F₁ hybridisation selectively express Ly-1.2 determinants, some selectively express Ly-2.2 determinants while the majority expresses neither. Similarly, Ia determinants selectively expressed on a very small subpopulation of lymphocytes (most likely T) in Ia^a haplotype mice and not on BW 5147 (Ia^k) are expressed in some of the hybrid clones derived from the (BALB/c × SJL)F₁ Ia^d/Ia^a haplotype spleen cells. Among normal T lymphocytes, selective expression of Ly and Ia determinants defines supopulations responsible for the various T-lymphocyte functions^{6,7}.

From the above, it is clear that the hybridisation of spleen cells with an appropriate established cell line (such as the BW 5147 T lymphoma) can yield continuous cell populations expressing characteristic T-cell surface markers. The preliminary evidence for expression of functional T-cell subset markers by these hybrid populations encourages us to examine them further for the presence of T-cell functions such as helper, suppressor and cytotoxic activity. It is apparent that the expression of any of these functions by clonal populations of continuous cell lines would greatly facilitate the analysis of these T cell-mediated functions.

The adjuvant active fraction of delipidated mycobacteria

FREUND'S complete adjuvant (FCA) has been used to influence both cell-mediated and humoral immune responses. Mycobacteria are the essential constituents of FCA and different active fractions have been extracted from mycobacteria of various strains¹⁻⁶. The purpose of the work reported here was to try to answer the following question: are cell-mediated and humoral immune responses related to the stimulatory effect of different bacterial components or to the adjuvant activity of a same bacterial fraction? Data presented here suggest that the stimulation of these two kinds of immunological response is related to the adjuvant activity of the same bacterial fraction, which has been identified as the lipoglycopeptide fraction extracted from mycobacterial delipidated cells (LG). Furthermore, the study of the relationship between adjuvant activity and chemical structure showed that LG is comprised of two distinct moieties: a glycopeptide moiety with cellular activity and a lipid moiety stimulating humoral immune response.

LG was isolated, by selective solubilisations, from bacterial products of the human 'Peurois' strain of *Mycobacterium tuberculosis* (Pasteur Institute, Paris) according to the procedure previously described⁷. Cleavage by alkaline hydrolysis⁸ of the ester linkage of LG resulted in two moieties: (1) a liposoluble moiety (37%) mainly composed of unsaturated fatty acids (mycolic acids) as determined by elementary analysis, solubility tests and comparison with the infrared spectrum of an authentic mycolic acid specimen; and (2) a hydrosoluble moiety (63%) identified by paper chromatography and infrared spectrometry, as a glycopeptide. This glycopeptide has the following characteristics: approximate molecular weight of 27,000 (determined by analytical ultracentrifugation); $[\alpha]_D^{20} = 36^\circ$; $C = 0.1$; neutral sugars: 94-98% arabinose and galactose in an approximate molar ratio of 1.6:2; amino acids and amino sugar: 2-6% glycine, alanine, glutamic acid, diaminopimelic acid and galactosamine. Catalytic hydrogenation⁹ of LG resulted in a derivative in which only unsaturated mycolic acids of the lipid moiety were saturated, called lipid moiety modified

derivative (LMD) or glycopeptide moiety non-modified derivative (GND) and acetylation of LG resulted in a derivative in which only free hydroxyl groups of the glycopeptide moiety were acetylated, called glycopeptide moiety modified derivative (GMD) or lipid moiety non-modified derivative (LND).

When LG was submitted to both catalytic hydrogenation and acetylation, a two-moieties-modified derivative was obtained, called LGMD (lipid and glycopeptide moieties modified derivative).

Female albino guinea pigs (400–500 g) were sensitised by injection into each hind footpad of 0.1 ml of a water-in-oil emulsion consisting of 1 part paraffin oil containing the adjuvant fraction, 2 parts Tween 80 and 5 parts saline containing the protein antigen, crystalline ovalbumin (OA). On day 21 after sensitisation, the animals were skin tested by intradermal injection of various amounts of OA in 0.1 ml saline into the clipped flank and the reactions were read 24 and 48 h later.

BD F₁ (DBA/2×C57BL/6) mice weighing approximately 20 g were each injected intraperitoneally with 10⁸ sheep red blood cells (SRBC) after about 15 min, various amounts of adjuvants in 0.1 ml of the water-in-oil emulsion were given by intraperitoneal injection. After 4 d, the animals were killed and the number of spleen cells forming or releasing antibody to SRBC was determined by the haemolytic plaque assay of Jerne and Nordin¹⁰, without modification.

Figure 1 illustrates the influence of LG and LND on the average number of plaque-forming cells (PFC) in mice 4 d after immunisation with SRBC. No positive reaction was observed in animals which had received LMD or LGMD as adjuvants.

Table 1 shows that inclusion of LG or GND in the antigen injection resulted in strong skin reactivity of delayed type hypersensitivity to the test antigen. No visible skin reaction was observed in animals sensitised with GMD or LGMD.

The results reported here show that in FCA, LG can substitute for whole mycobacterial cells. LG comprises two moieties: a hydrosoluble glycopeptide moiety and a liposoluble lipid moiety. The glycopeptide moiety is responsible

for the cell-mediated response, and the humoral immune response is attributed to the lipid moiety. The ability of LG to act as an adjuvant of both cell-mediated and humoral immune responses seems to be related to some state of balance between these two moieties, since (1) a decrease in hydrosolubility of the glycopeptide moiety by acylation of free hydroxyl groups destroyed cellular activity of LG; (2) an increase in liposolubility of the lipid moiety by catalytic hydrogenation inhibited humoral immune response; and (3) the derivative LGMD in which both lipid and glycopeptide moieties were modified, was found to be completely inactive as an adjuvant for either cell-mediated or humoral immune responses.

IgM-IgG switch-over among antibody-forming cells in the mouse

DIFFERENTIATION of immunocytes from stem cells to antibody secreting B cells involves sequential expression of genes coding for heavy chain constant regions. This differentiation seems to be independent of thymus activity and antigen stimulation, for nude mice¹ and 15-week human foetuses² as well as germ-free mice³ and piglets⁴ have proportions of surface IgM, IgG or IgA bearing cells similar to those found in normal adults. It has therefore been suggested that the switch-over from IgM to IgG and IgA expression occurs before antigen contact which leads to differentiation from small B lymphocytes to plasma cells⁵. But during antibody production after antigenic stimulation a small proportion (1–3%) of mouse plaque-forming cells (PFC) secrete both IgM and IgG (refs 6, 7) and clones of cells derived from a single antigen-stimulated precursor secrete both IgM and IgG antibody⁸. These observations indicate that the IgM→IgG switch could be antigen driven. We have investigated the two alternatives by culturing

individual PFC from mice immunised with sheep erythrocytes (SRBC) to study whether daughter PFC produce the same or a different Ig class. We have found that a part of IgM producing parental PFC can generate 'in vitro' IgG

Fig. 1 Generation of daughter PFC producing either IgM or IgG from individually cultured parental PFC taken on the indicated days after immunisation ●, Parental IgM PFC generating IgM daughters; □, parental IgG generating IgG daughters; ▲, parental IgM generating IgG daughters. *a*, The numbers of daughter PFC are recorded per 100 individually cultured parental PFC (standardised % from 96 to 186 parental PFC at each point). *b*, Relative contribution of various daughter PFC in the total amount of daughter PFC in each day after immunisation. Spleen cells from Swiss mice given SRBC (4×10^8) on day 0 were taken on days 2, 3, 4 or 5 and placed in non-shaken mass cultures as described previously⁹ for selecting the most resistant PFC in 'in vitro' conditions. These cultures were supplemented with LPS at a final concentration of $7.5 \mu\text{g ml}^{-1}$. The cells were taken 24 h later, mixed with SRBC and complement, distributed in 5- μl microdroplets covered with paraffin oil and incubated for 45 min at 37°C . Individual PFC (parental PFC) were micro-manipulated out of the droplets and transferred into separate wells of polyacrylamide plates^{10, 11}. These wells had each been preseeded with about 1,000 heavily irradiated (2,500 rad) normal Swiss mouse spleen cells and 1,000 SRBC. The whole plate was sunk into plastic Petri dishes (Falcon) containing medium made half with the medium taken from the preseeded culture and half with fresh medium. The plates were maintained for 24 h in cell culture conditions and the content of each well was spread together with indicator SRBC and complement on antibody slides (Bellco) incubated for 1 h at 37°C and examined for haemolytic plaque formation (daughter PFC). For investigating the Ig class switch over from the parental to daughter PFC, the parental and daughter PFC were detected either directly (IgM producers) or indirectly using an enhancing serum a rabbit anti-mouse IgG serum mixed with a goat anti-mouse- μ -chain serum for revealing only IgG producing PFC. Control wells containing irradiated cells and SRBC as well as old and fresh culture fluids but not micromanipulated PFC were left in each experimental plate. In a total of over 350 such wells not all PFC were detected.

producing daughters, but this switch occurs only during the first 3 d after immunisation.

Adult mice were immunised with SRBC, their spleens were taken in the following days and cultured for 24 h in mass-cultures and then the PFC were micromanipulated and individually cultured for the subsequent 24 h in the conditions described in Fig. 1. The cultures contained LPS (*Escherichia coli* 055B5 lipopolysaccharide, Difco) for mitogenic stimulation in absence of T-cell helper activity in the individual PFC cultures. Three series of experiments were undertaken: in the first IgM producing (direct) parental PFC appearing in the mass-cultures were individually cultured and then plated with the direct procedure for revealing IgM producing daughter PFC; in the second series, the parental and daughter PFC were revealed with the indirect procedure using an enhancing an anti-mouse IgG serum mixed with an anti-mouse μ -chain serum (Table 1); in the third series, again IgM producing parental PFC were individually cultured but the daughter PFC were revealed by the indirect method for detecting only IgG producers so as to study the IgM $\rightarrow$ IgG switch from parental to daughter PFC.

In this type of experiment not all individually cultured PFC yield a progeny. In fact, only 10–20% of parental PFC generate daughter PFC (refs 11, 13). But, the percentage of parental PFC yielding daughter PFC and especially the number of the latter (1–5 per parental PFC), can give a representative figure of the proliferative potential of each category of parental PFC. As shown in Fig. 1*a* day 3 parental IgM PFC generated the higher number of IgM daughters (51%) and thereafter their yield decreased whereas the 4th day IgG parents produced the higher number of IgG daughters (44%). The generation of IgG producing daughter cells from day 2 and day 3 parental IgM producers was rather low (10% and 12.5% respectively) and sharply decreased thereafter (1.5% from day 4 and 0% from day 5 parental IgM PFC). It was, however, significant because the relative contribution of IgG daughters of IgM PFC seems quite considerable, about the half on day 2 and the third on day 3 in the total number of IgG producing daughters of IgG and IgM parental PFC (Fig. 1*b*). On the other hand, it seems that not all IgM PFC can generate IgG daughters: 21% of day 3 parental IgM PFC (39 out of 186) produced IgM daughters (total, 95; 51%) whereas only 8.7% (14 out of 160) of day 3 parental IgM PFC generated IgG daughters (total 20; 12.5%). This is in agreement with observation that a proportion of lymphocytes bear surface IgM only whereas others express both IgM and IgG or IgM and IgA before expressing the latter alone¹. The low numbers of IgG daughters of IgM PFC detected may be due to the generation of both IgM and IgG daughters from these IgM parental PFC. It is also likely that these parental PFC already began to synthesise low quantities of IgG. These possibilities could not be tested using our methods because parental and daughter PFC endowed with high rate synthesis and secretion of Ig could only be revealed by either the direct or the indirect method.

To what extent do the above findings correspond to the 'in vivo' events? To answer this question we compared the relative frequency of IgM and IgG producing daughter PFC with that of IgM and IgG PFC found in 'in vivo' studies. Wortis *et al.*¹⁴ observed that on the 3rd day after immunisation of mice with SRBC, 47% of PFC produced IgM and 53% IgG and on the 5th day 38% and 62% respectively. Sell *et al.*¹⁵ did not find significant numbers of IgG PFC on day 3 whereas on day 5 they found 42% IgM PFC and 58% IgG PFC. Compared with these figures we recorded 59% IgM and 41% IgG daughters of day 3 parental PFC and 39% and 61% respectively from day 5 parental PFC (Fig. 1*b*). Therefore it could be inferred that this sampling of daughter PFC is not very different from that found 'in vivo' at correspond-

Table 1 Numbers of haemolytic PFCpcr 10^6 spleen cells taken on day 2 or 5 after immunisation of mice with SRBC

*Rabbit anti-mouse IgG serum (Pasteur Institute, Paris) exhibiting its maximum enhancing activity at the dilution of 1.3,200.

†Goat anti-mouse IgM serum (Meloy) made monospecific anti- μ -chain by absorption with mouse IgG in the laboratory and giving in immunoelectrophoresis a single arc of precipitation corresponding to mouse IgM (ref. 12).

ing intervals after immunisation with SRBC. This parallelism does not exclude the possibility that the IgM→IgG switch described here is induced by LPS present in the cultures since it has been shown the LPS alone accelerate expression of surface and cytoplasmic IgG¹⁶. Secretion of IgG 'in vitro' does not appear until 2 weeks after onset of LPS stimulated mouse spleen cell cultures¹⁷, however.

The considerable frequency of IgG PFC daughters of day 2 IgM PFC (44% of total IgG daughters, Fig. 1b) may mean that on day 0 of primary stimulation only IgM precursors are triggered by antigen. The more so as treatment of cells with anti-mouse μ -chain serum when culturing them¹⁸ or transferring them into irradiated recipients¹⁹ results in inhibition of IgM as well of IgG and IgA antibody production. Cells already committed to IgG could also be triggered by antigen during primary (Fig. 1) or during secondary response²⁰, however and generate progeny of IgG producing cells. It is therefore possible that even during the primary response a part of IgG producers are derived from IgG precursors.

Lawton *et al.*⁵ studying the development of Ig class diversity concluded that the switch from IgM to IgG expression occurs before antigen contact. Our results showing that early after antigen stimulation a part of IgM PFC generate IgG producers suggest that the cells are sensitive to antigen before the full accomplishment of the commitment to one particular Ig class production. The process of sequential expression of genes coding for C_H could, however, be independent of the antigen-driven differentiation from B lymphocytes to plasma cells. Indeed findings that germ-free mice³ and piglets⁴ have normal adult proportions of cells bearing μ , γ or α surface Ig as well as present evidence that on days 4 and 5 after immunisation no IgM→IgG switch occurs in spite of the existence of many proliferating IgM PFC and the presence of antigen (Fig. 1) strongly suggest that IgM→IgG switch is rather directed by an internal genetic control. It may in fact be that B cells become sensitive to antigen as early as Ig (IgM) molecules appear on their surface, the switch-over to IgG or IgA production taking place whether or not antigenic stimulation intervenes.

Simple model for self-non-self-discrimination in invertebrates

THE immune mechanisms which enable invertebrates to eliminate infectious agents are not well understood. There have been many reports, however, that invertebrates produce 'recognition factors' which interact with foreign substances and subsequently aid the phagocytosis of these substances^{1–5}. Such recognition factors have been isolated from worms, molluscs, arthropods, echinoderms and protochordates, and have been shown to have agglutinating and bactericidal activities as well as opsonic properties. But, unlike the vertebrate immune system, there is little evidence for a memory component in the production of these factors^{3–5}. The recognition factors are usually large molecules which can be readily dissociated into subunits and which in no way resemble the immunoglobulins present in vertebrates^{3–12}. They apparently have specificity for carbohydrate structures and, in many cases, an individual has several distinct subpopulations of recognition factors which bind different sugar specificities^{3–12}. The recognition factors seem to be synthesised by haemocytes in the haemolymph^{13,14}. After secretion they can, in many invertebrate species, bind to the surface of haemocytes as well as persist in a soluble form in the haemolymph^{3–5,14–18}. Both the soluble and cell-bound forms of the recognition factors can augment the phagocytosis of foreign substances. Thus, the invertebrates have evolved a simple recognition system which enables them to discriminate between 'self' and 'non-self'. In this paper I propose that the recognition factors are composed of some of the glycosyl transferases which the invertebrate uses to synthesise its own carbohydrate side chains. Such a model guarantees the maintenance of rigid self non-self discrimination.

The model is presented schematically in Fig. 1 and would particularly apply to the advanced invertebrates. It is arbitrarily proposed that the invertebrate synthesises an oligosaccharide side chain of five sugar residues. Each sugar residue is attached by a different glycosyl transferase which has specificity for the sugar acceptor¹⁹. Thus, five proteins (transferases) with different sugar binding properties are

present in the organism. These five transferases act as the subunits of the recognition factors, are secreted by haemocytes into the haemolymph, and randomly associate into hexamers.

The recognition factors do not react against self as the self sugars they recognise have been blocked by glycosylation. This important point is made clearer if the mode of action of glycosyl transferases is considered (Fig. 2). These enzymes catalyse the transfer of a monosaccharide from a sugar nucleotide to the terminus of a specific sugar acceptor¹⁹. Figure 2 depicts the enzyme-substrate reaction of glycosyl transferase 4 in Fig. 1. It can be seen that transferase 4 interacts with terminal monosaccharide 3 and catalyses the attachment of monosaccharide 4. Of course, once glycosylation has occurred, monosaccharide 3 is blocked from further interaction with transferase 4. Thus, the glycosyl transferases which make up the recognition factors are unable to bind to self as the terminal sugars they recognise have been masked by glycosylation. In addition, it should be noted that the recognition factors would probably only bind foreign substances and not glycosylate them (as in Fig. 2) as it is most unlikely that sugar nucleotides exist extracellularly in the haemolymph.

In the model presented in Fig. 2, it is proposed that polymerisation of the transferases into a recognition factor is initiated by an additional protein (no. 6) which has an acceptor site on the haemocyte surface. The inclusion of this additional protein imparts cytophilic and opsonic properties to the recognition factors. In order to prevent inter-

Fig. 1 A possible model for the recognition factors in invertebrates which augment the phagocytosis of foreign substances. Various monosaccharides on the haemocyte surface, which constitute an oligosaccharide side chain, are represented by circles, diamonds and squares and are numbered 1-5. Each monosaccharide is inserted in the oligosaccharide by a specific glycosyl transferase (proteins numbered 1-5) as depicted in Fig. 2. Thus, transferase 2 binds to monosaccharide 1 and catalyses the attachment of monosaccharide 2, transferase 3 binds to monosaccharide 2 and facilitates the attachment of monosaccharide 3, and so on. The transferases randomly associate into recognition factors (hexamers), this polymerisation being initiated by an additional protein (no. 6). Protein 6 has an acceptor site on the haemocyte surface which enables the recognition factors to be cytophilic for haemocytes. For details of the model see text.

Reaction product

Fig. 2 Mode of action of glycosyl transferases. A trisaccharide sugar acceptor is depicted, linked to a lipid or protein carrier (R). The circles, diamonds and squares represent the different monosaccharides. The glycosyl transferase specifically binds to the terminal monosaccharide (◆) of the sugar acceptor and catalyses the transfer of a monosaccharide (○) from its uridine diphosphate (UDP) donor to the terminus of the acceptor. The resultant reaction product is a tetrasaccharide. This diagram depicts the enzyme-substrate reaction of glycosyl transferase (no. 4) in Fig. 1, that is, the transferase which binds to monosaccharide 3 and catalyses the attachment of monosaccharide 4.

action (and therefore autoaggression) between haemocytes, only one cytophilic subunit can be included in each hexamer.

Although there are only five basic recognition units in this model, the fact that they polymerise in a random manner into hexamers, enables them to react in a multi-point fashion with foreign substances. This greatly increases the effective specificity range of the recognition factors as it is well established that multipoint interactions have a much higher binding efficiency than single point interactions²⁰.

This model of immune recognition has several important theoretical advantages. First, it ensures that self-reactive recognition factors are not generated. Second, due to multi-point binding, a comparatively wide range of foreign antigenic specificities can be recognised. Third, the system can withstand a high degree of genetic polymorphism without self-reactivity appearing. Fourth, if any infectious agent produces hydrolytic enzymes which degrade the cell surface carbohydrates of the invertebrates host, the subterminal sugars are unmasked and thus these damaged and infected cells can be readily recognised and encapsulated by the host's haemocytes.

The model presented in Fig. 1, however, could vary in several ways. Obviously, the variety of glycosyl transferases and the number of subunits incorporated into the recognition factors could vary considerably between invertebrate species. Furthermore, the cytophilic subunit may be absent in some invertebrates and, in these cases, the factors may eliminate infectious organisms by merely acting

as lytic and neutralising agents. Similarly, only some of the glycosyl transferases produced by the invertebrate may be secreted and incorporated into recognition structures. Conversely, not all the glycosyl transferases appearing in the recognition factors may be able to act as glycosylating enzymes. For example, if a mutant form of enzyme 3 arose (see Fig. 1) which had lost its glycosylating activity, then enzymes 4 and 5 would be unable to construct a sugar side chain, even though their enzymatic properties were still intact.

There would be no memory component in this form of immune recognition. It is conceivable, however, that infectious agents may activate the haemocytes to multiply and secrete the recognition factors more rapidly. There is, in fact, some evidence in invertebrates that foreign substances can induce the production of recognition factors^{3,5,21,22}. Whether the recognition factors described above mediate the specific transplantation immunity observed in some invertebrate species remains to be determined^{3,5,23,24}. The existence of specific short-term memory in these transplant responses suggests, however, that another recognition system, possibly the forerunner of vertebrate T-cell immunoglobulin, may be involved²⁵.

In conclusion, it should be noted that there is a mounting body of evidence which suggests that, in both plants and animals, glycosyl transferases have a role in cell-cell recognition and cell-glycoprotein interactions^{19,26,27}. These findings add credence to the possibility that glycosyl transferases could have developed into a primitive protective system against infectious agents. In fact, some of the sugar binding proteins detected in vertebrates, such as the galactose-binding proteins in liver which mediate the clearance of desialysed plasma proteins^{20,28,29}, may represent a remnant of the invertebrate recognition system described.

Succinyl bee venom melittin is a leukocyte chemotactic factor

A NUMBER of leukocyte chemotactic factors of defined structure have been described. They include formyl-methionyl tripeptides (f-Met-Leu-Phe and related peptides) which attract neutrophils at concentrations as low as 10^{10} – 10^{11} M (refs 1 and 2), the eosinophilotactic tetrapeptides Val-Gly-Sur-Glu and Ala-Gly-Ser-Glu (ECF-A) (ref. 3) and

HETE; a 12-hydroxy-unsaturated fatty acid derivative of arachidonic acid⁴. All of these have in common a net negative charge and a hydrophobic moiety. The availability of chemotactically active molecules of known structure now allows structure-activity relationships to be examined, and preliminary evidence that f-Met peptides bind to a receptor on the leukocyte surface has been presented^{5,6}. Leukocytes respond to a great many chemotactic factors of diverse structure and, in order to understand fully the binding sites involved, it will be useful to have as many defined chemotactic factors for study as possible. This paper reports the chemotactic activity of the succinylated form of the bee venom peptide, melittin.

Figure 1 shows the structure of melittin⁷. It is a cationic, amphipathic peptide in which residues 1–20 are predominantly hydrophobic and residues 21–26 hydrophilic. Melittin is surface-active and has been shown to disrupt cell membranes and artificial phospholipid liposomes^{8,9}. Unmodified melittin is lytic for neutrophil leukocytes at concentrations of 10^{-6} M and above⁸, and I was unable to detect any chemotactic activity for unmodified melittin at any concentration. Habermann and Krowallek¹⁰ showed that the cytolytic effects of melittin could be abolished if the α - and ϵ -amino groups were blocked by succinylation, thus reducing the positive charge. Since succinylation would yield a product with broadly similar physicochemical characteristics to the chemotactic factors listed above, it might be predicted that succinyl-melittin (S-melittin) would have chemotactic activity for leukocytes.

Lys – Arg – Lys – Arg – GluNH₂ – Glu(NH₂)₂

Fig. 1 Structure of melittin.

Figure 2 shows that a pure preparation of S-melittin attracts human blood neutrophil leukocytes into micropore filters in a dose-dependent manner. To demonstrate that the cells were responding to a gradient of S-melittin and thus that S-melittin determined the direction of their locomotion (chemotaxis) and not merely their rate of locomotion (chemokinesis), the activity of S-melittin was examined in a checkerboard assay, a procedure introduced by Zigmond and Hirsch¹¹ to distinguish between these two reactions.

Table 1 shows that the leukocytes responded to both the absolute concentration of S-melittin and to the concentration gradient, thus showing both reactions. Assuming that melittin exists as a tetramer⁷, its effective concentration was between 5×10^{-5} M and 5×10^{-6} M. Only heavily succinylated preparations of melittin were sufficiently non-cytotoxic to show chemotactic effects and at least 80% of free amino groups required to be blocked to obtain a chemotactically active peptide.

Melittin contains neither methionine nor phenylalanine, and thus does not contain any sequence similar to those of the f-Met peptides which are active as chemotactic factors. If these peptides act by binding to a stereospecific cell surface receptor, it is unlikely that S-melittin binds to the same receptor. It is more probable that the leukocyte surface contains more than one site at which chemotactic reactions can be initiated. The effective chemotactic concentration of S-melittin was lower (ED_{50} about 5×10^{-6} to 10^{-5} M) than that of f-Met tripeptides suggesting a lower binding affinity. The locomotor response induced by the ED_{50} was, however, comparable in both cases.

Since melittin is known to bind to lipid bilayers both in cells and in liposomes, it is suggested that this binding, which could be to a saturable binding site but is not likely

Fig. 2 Migration of human blood neutrophils into micropore filters (3-μm poresize, Millipore) towards S-melittin at various concentrations below the filter. Cells were prepared in Gey's solution with human serum albumin (1 mg ml⁻¹) and the chemotaxis assay was carried out as described previously¹³ using the leading-front method¹¹ to measure migration. Bee venom melittin was a highly purified product obtained from Dr Barbara Banks, University College, London, UK. It was treated with succinic anhydride (35 mg per 20 mg peptide) as described by Habermann and Krowallek¹⁰. The ninhydrin reaction¹⁴ was used to determine free amino groups before and after succinylation. The preparation used in the experiment shown had 83% of its free amino groups blocked.

to be to a stereospecific receptor, is an adequate signal for initiation of chemotactic reactions. I have presented a similar hypothesis to explain the chemotactic properties of denatured proteins and proteins with diverse covalently bonded non-polar groups¹². It now seems likely that chemotactic reactions can be initiated by signals from molecules binding to the cell surface at a variety of sites and with a variety of affinities. This versatility seems reasonable in view of the wide diversity of molecules now shown to initiate such reactions¹³. The charge of surface-active chemotactic factors such as S-melittin is obviously important as well as their hydrophobicity, since blocking the amino

Table 1 Migration of human blood neutrophils in various absolute concentrations and concentration gradients of S-melittin

S-melittin μg ml ⁻¹	Migration (μm into 3-μm poresize filter in 75 min)				
	0	5	95	185	275
0	52				
5		54	82(62)	89(70)	102(65)
95			58(63)	71	95(73)
185				68(73)	75
275					57(78) 76(81) 91

Figures on the diagonal from upper left to lower right show migration in increasing absolute concentrations of S-melittin but in the absence of a gradient. Above the diagonal, cells were moving in a positive gradient, below it in a negative one. The figures without brackets show the migration actually observed, those within brackets show the migration expected if the cells had been responding to absolute concentration alone (calculated after Zigmond and Hirsch¹¹). Note that cells migrated further in positive gradients and less far in negative gradients than would be expected if they had responded only to the absolute concentration of the attractant suggesting that there was a chemotactic response to the S-melittin gradient.

groups of melittin with negatively charged succinyl groups yields a product which is chemotactic at concentrations at which the unconjugated, cationic, analogue damages the cell.

Theophylline-induced changes in ion transport and conductance in human small intestinal mucosa

THE central role of cyclic 3',5'-adenosine monophosphate in intestinal secretion has been emphasised recently^{1,2}. Electrolyte absorption is converted to secretion^{3,4} and mucosal conductance is reduced^{5,6} by increases in epithelial cyclic AMP concentrations and this is held to mediate the profound secretion provoked by cholera and other forms of infective 'toxigenic' diarrhoea. The mechanisms of the intestinal response to cyclic AMP are incompletely understood and we therefore examined this response in human intestinal mucosa. We report here that changes in mucosal permeability are largely determined by the state of the lateral intercellular spaces. When these spaces are open, permeability is increased by cyclic AMP and when they are closed, permeability is decreased. These changes in permeability have a profound effect on the ion transport responses to cyclic AMP.

In ileal mucosa theophylline induced a rapid rise in electrical potential difference (p.d.) and short circuit current (s.c.c.) persisting for at least 40 min (Fig. 1). Total ionic conductance, calculated from p.d. and s.c.c., fell by about 25%, an effect similar to that observed in rabbit ileum⁶.

This conductance fall has been attributed to effects on paracellular shunt pathways and one possible anatomical counterpart is the elimination of lateral intercellular spaces which follows cell swelling induced by theophylline⁶. This high conductance pathway normally contributes about 80% of total epithelial conductance⁶, and closure of the channels could clearly influence total conductance. If this hypothesis is correct, then opening the spaces should prevent this response to theophylline. We therefore re-examined the influence of theophylline in the presence of glucose (15 mM) which dilated the lateral spaces due to enhanced fluid absorption (Fig. 2). Here, instead of rising, the mucosal resistance, the reciprocal of conductance, fell from 37 to 21 Ω cm⁻² (Fig. 1). 3-O-methyl glucose also caused theophylline to lower ileal resistance from 41 to 26 Ω cm⁻² and 35 to 28 Ω cm⁻² in two studies. Since 3-O-methyl glucose is transported but not metabolised, this response is not a non-

specific metabolic effect of glucose. It also occurred with glucose on the mucosal, but not with it present solely on the serosal side of the tissue, confirming an association with transport. Glucose alone did not influence resistance, but did so when added to tissues pretreated with theophylline (Fig. 1).

The simplest explanation for these findings is that dilatation of lateral spaces revealed a theophylline-induced increase in conductance. This would bring intestinal mucosa into line with high resistance epithelia such as toad bladder, in which theophylline enhances conductance¹⁰. Theophylline thus apparently has two effects—decreasing conductance due to cell swelling and closure of lateral spaces, and increasing it when the lateral spaces are opened by glucose. Similar changes were found in rat ileum by Walling and Kimberg (personal communication), but others have not demonstrated this effect in rabbit ileum exposed to cholera toxin¹¹. This discrepancy may be due to species differences, but is otherwise unexplained.

There is some conflict about the mechanisms for the

intestinal secretion. Nellans *et al.*¹² demonstrated that theophylline inhibits a coupled Na-Cl influx at the luminal cell membrane while Powell *et al.*¹³ presented convincing evidence for the stimulation of a coupled Na-Cl secretion in rabbit ileum. Yet others have postulated that theophylline stimulates a rheogenic secretion of Cl, uncoupled from Na (ref. 14). Since mucosal conductance influences electrolyte transport we examined the effect of theophylline on ion

Fig. 2 Electron micrograph of ileal mucosa after exposure to theophylline in the absence of glucose (a) and in its presence (b). Note the dilated intercellular spaces in the latter.

Fig. 1 Electrical responses of stripped human ileal mucosa to theophylline (10^{-2} M). Theophylline (Theo.) raises mucosal cyclic AMP concentrations by inhibiting its breakdown. Fresh mucosa, removed at operation for a variety of diseases, was separated from abnormal areas, stripped of muscle and serosa and mounted in Ussing type flux chambers as described previously⁸. In *a* glucose was absent from the bathing solutions; in *b* it was present throughout (15 mM), and in *c* it was added 40 min after the theophylline. In each case the p.d. (●) and s.c.c. (★) rose in response to theophylline but the calculated tissue resistance (*R*) (○) rose in the absence of glucose and fell in its presence. Glucose alone did not influence resistance but it fell when glucose was added after theophylline (*c*) indicating that this effect is dependent on the presence of both glucose and theophylline.

Table 1 Influence of theophylline (10^{-2} M) on ion transport ($\mu\text{mol cm}^{-2} \text{h}^{-1}$) in stripped ileal mucosa in glucose-free and glucose-containing media and across jejunal mucosa in glucose-containing media

transport in the presence and absence of glucose (Table 1). In glucose-free buffer theophylline converted a net ileal absorption of sodium to a significant net secretion and chloride secretion was also induced. These changes were due to an increase in unidirectional flux from serosa to mucosa and a reduction in the opposite flux. The results are compatible with both an inhibition of a neutral sodium chloride influx and stimulation of a sodium chloride secretion. But, the decreased epithelial conductance could conceivably account for the reduced Na-Cl influx without invoking any other inhibitory mechanism. However, the increased flux towards the mucosa occurred despite the decreased conductance and the evidence for this secretory process is thus more certain.

Somewhat different results were obtained when glucose was present (Table 1). Here net chloride absorption was changed to secretion but net sodium transport was not significantly reduced. Thus it is possible that theophylline stimulated an uncoupled Cl secretion when glucose was present. The rise in s.c.c. induced by theophylline with glucose ($150 \mu\text{A cm}^{-2}$) was greater than without it ($100 \mu\text{A cm}^{-2}$) in these unpaired studies, possibly due to the separation of anion and cation transport and supporting the possibility of a rheogenic Cl secretion. Furthermore, Sheerin and Field¹⁵ observed that the pH of solutions bathing rabbit ileum influenced the sodium but not the chloride transport response to theophylline. The dependence of sodium secretion on pH suggests that it is not closely coupled with chloride secretion. An uncoupled chloride secretion in response to acetylcholine has also been demonstrated in human intestinal mucosa¹⁶.

But, the evidence for an uncoupled Cl secretion depends critically on the apparent failure of theophylline to influence Na transport in the presence of glucose. It remains possible that the marked movement of sodium from mucosa to serosa induced by glucose masked a relatively small reversal of sodium movement by theophylline.

The increased unidirectional flux of Na-Cl towards the mucosal side due to theophylline plus glucose, might reflect the increased conductance of mucosa. The increase in Cl flux was greater than that in Na (4.5 compared with $3.0 \mu\text{mol cm}^{-2} \text{h}^{-1}$). But, while this discrepancy could be

due to the additional stimulation of a mucosally-directed Cl pump, it could equally be due to a change in the relative conductance of Na and Cl (ref. 6).

Glucose-stimulated bulk fluid transport probably induces appreciable solvent drag forces which increase the mucosa to serosa flux of ions while decreasing that in the opposite direction. This would be more obvious when mucosal conductance is increased. In contrast to this prediction, the Na-Cl flux from mucosa to serosa remained unchanged, suggesting that theophylline might be inhibiting this flux.

In summary, these observations suggest that theophylline exerts several effects. First, it stimulates a sodium and chloride secretory process, seen best in the absence of glucose. This Na-Cl secretion may be a neutral coupled process but a rheogenic chloride secretion may also be revealed in the presence of glucose. In addition, a Na-Cl absorptive flux may be inhibited as deduced from the experiments performed in the presence of glucose.

Finally, it is of interest that human jejunal mucosa also actively secretes chloride in response to theophylline (Table 1) despite the fact that chloride movement here is entirely passive in control conditions, *in vivo*¹⁷ and *in vitro*¹⁸.

Fast motor units are not preferentially activated in rapid voluntary contractions in man

MOST mammalian muscles include muscle fibres of different histochemical types which are organised in separate motor units (a motor unit is a group of muscle fibres innervated by a single motoneurone) with different physiological characteristics¹. When a muscle carries out a slowly graded contraction, the motor units of the slow type are activated before the motor units with a faster contraction time which are also the ones developing more force since they include a larger number of muscle fibres². This orderly recruitment can also be shown in intact man in whom the spike-triggered averaging method further allows the extraction of the mechanical twitch of a single motor unit from the whole muscle force³. In view of the versatility of the human hand movements and considering recent inferential views about variations in the recruitment order of motor units^{4,5}, we had anticipated that the fast motor units could be preferentially recruited in brisk voluntary contractions. This expectation is not borne out by the results presented. On the contrary we found the faster motor units to be recruited after the slow motor units, even in fast contractions.

A total of 54 single motor units were studied in the first interosseus muscle of the hand in five normal adult subjects. Highly selective bipolar electrodes were inserted through the skin and carefully positioned in the muscle belly so as to pick up selectively the action potentials of two to five different motor units at a single site. Each motor unit was clearly identified from background activities, even during strong rapid contractions. The hand was firmly held in a sturdy receptacle. The isometric force for abduction of the index finger was transduced with an Elf-1000-250 Flatline load cell. The mechanical twitch of each motor unit was extracted from the isometric myogram of the steadily contracted muscle by averaging the (FM tape recorded) analogue force signal. The action potential of the chosen motor unit was selected by a window trigger electronic circuit and made to initiate the duty cycle of a Nicolet model 1074 averaging digital computer. Several periods of steady contraction of the muscle were used in order to avoid fatigue effects. Due precautions were taken to automatically exclude mechanical interference from close-range firing of the unit⁶.

The isometric twitches with different contraction kinetics (time-to-peak 65 and 39 ms respectively) shown in Fig. 1; *a, b* correspond to two different motor units recorded with the electrode in the same position in the muscle. When the subject contracts his muscle progressively so that the force increases slowly as a ramp function reaching its peak in about 10 s, the slower contracting unit is activated first, and the faster unit is not recruited until several seconds later when the contraction force exceeds 280 g in this example. The sequence is highly reproducible for each recording site⁶.

In brisk contractions the timing of the motor units discharges is difficult to relate with precise levels of the fast-rising muscle force. But a consistent force threshold

of any chosen motor unit can be estimated by requesting the subject to produce a large series of very brief ballistic contractions, each achieving different peak forces from about 10 to 2,000 g. A given unit never discharges for brisk contractions below a certain peak force, while it always fires for contractions with peak force above that value. The method thus facilitates measurement of a true ballistic force threshold which is consistent in repeated trials⁷. The sample records of Fig. 1 *d-g* show that the smaller unit failed to discharge for the weakest contraction (*d*), but was activated in all others, while the larger unit only started firing when the ballistic peak force exceeded 80 g (*g*).

Fig. 1 Recruitment order and force threshold of two motor units in the first interosseus muscle. Normal subject, 28 yr old. The selective recording electrode allowed the action potentials of these two units to be clearly isolated from background activities. The isometric twitch of each unit was extracted by spike-triggered averaging of 512 discharge samples and presents a contraction time (time-to-peak) of 65 ms (*a*) and 39 ms (*b*) respectively. The peak forces are 0.3 g (*a*) and 1.5 g (*b*). The corresponding averaged action potentials (AP) are shown on the same time scale above the myogram (MG). *c*, Voluntary contraction of the interosseus muscle as the subject is tracking a slowly rising force ramp which achieves 300 g in about 10 s. The slower motor unit (illustrated in *a*) starts discharging when the ramp force reaches 20 g while the other motor unit which can easily be identified by its action potential waveform presenting a larger positive-going (downward) component (see *b*, 'AP') only starts discharging later, when the ramp contraction reaches 280 g. *d-g*, ballistic voluntary contractions recorded during the same experiment. The isometric peak forces are 10 g (*d*), 20 g (*e*), 50 g (*f*) and 110 g (*g*) respectively. The contraction in (*e*) just exceeds the ballistic force threshold of the slower motor unit studied. The ballistic contraction in (*g*) recruits the faster motor unit.

For each of the single motor units studied, we obtained complete data for the twitch contraction time, and for the force thresholds respectively in graded ramp and ballistic contractions. Confirming previous results⁴, we found that all the units with a higher ramp threshold were fast contracting. The units with a low ramp threshold were either fast or slow contracting but a significant relation was observed between the two features ($r_{xy} = -0.62$) (Fig. 2a). For the brisk contractions, we found the relation between ballistic force threshold and the twitch contraction time to be rather similar and also quite consistent ($r_{xy} = -0.54$) (Fig. 2b).

The pooled data of Fig. 2 do not allow us to exclude any possible change in recruitment order in the two types of voluntary contractions. This has been achieved by considering pairs of motor units recorded during the same trials from a given position of the recording electrode in

Fig. 2 Relation between the contraction time of the twitch of 54 different single motor units recorded in the first interosseus muscle (ordinate), and the force threshold of each unit (abscissa, logarithmic scale) estimated either with a slow tracking ramp contraction (a), or with brisk ballistic contractions (b). The calculated regression lines fit the functions: $y \text{ (ms)} = 34 - 13 \log x \text{ (kg)}$ (a) and $y \text{ (ms)} = 30 - 13.4 \log x \text{ (kg)}$ (b) respectively. The graph also shows that the absolute force thresholds are smaller in ballistic than in ramp contractions.

the muscle. Since the specific question considered was whether any reversal of recruitment occurred in brisk contractions, the motor unit pairs considered were required to present significantly different twitch kinetics which we arbitrarily chose to define as a difference of at least 8 ms (range 8–56 ms; mean 23 ms) between their respective contraction times. Twenty-two pairs were retained which satisfied the further criterion that, for any pair, the slower unit had been recruited before the faster unit of the pair in the slow ramp contractions. This was obviously required to answer the question whether any preferential activation of the faster unit occurred in ballistic contraction. However, we did not observe a single instance in which the faster unit of the pair was recruited before the slower unit when the subject produced a brisk ballistic movement instead of a slow tracking ramp.

The wide repertoire of voluntary movements in man and the capacity for brisk and accurate finger displacements is related, amongst other things, to the richness of corticomotoneuronal (pyramidal) connections^{9,10}. When man contracts a muscle so as to track a slowly rising ramp force, the recruitment order of the single motor units is consistent and stereotyped^{6,8} (Fig. 2a). Such movements, even though they are carried out through pyramidal commands on the segmental α motoneurons, involve a co-activation of the γ motoneurons which contract the spindle muscle fibres and thereby elicit an important excitatory drive through the γ loop on to the same α motoneurons¹¹. Spindle afferents feedback excitation was shown in animals to recruit small α motoneurons before larger ones, according to Henneman's size principle^{3,12}. It is thus not surprising that ramp voluntary contractions in man should also obey the size principle. By contrast, when man executes brisk contractions as fast as possible, the pyramidal commands to the α motoneurons must be pre-programmed so as to produce the required ballistic force, and there is no time for any corrective feedback action from spindle or other afferents¹². In such conditions, the synaptic input to these α motoneurons is different from that in ramp contractions, and we expected to find more flexibility in the recruitment order, if only for allowing fast contracting motor units to be preferentially activated in brisk movements, but our present data definitively exclude such an hypothesis. Both slow and fast motor units containing fibres of either histochemical types respectively occur in the human interosseus muscle¹⁴. The muscle fibre typing is known to be related to the motoneurone properties, including cell size¹. Our findings suggest that the significance of the histochemical and functional types of motor units (slow and fast) should be related, not to any selective usage in either slow or fast voluntary movements in man, but rather to the more frequent activation of the smaller motoneurons according to the size principle¹⁵.

TEA binding sites in crayfish axon membranes

VOLTAGE-DEPENDENT ion channels are the basis of nerve impulse propagation along the axon. The mechanism of gating and ionic selectivity of these channels remains obscure as long as the membrane molecules participating in these processes are unknown. Some biochemical properties of a tetrodotoxin binding component of the sodium channel have been determined¹, but for the potassium channel not even the number of channels per unit axon surface is known. From noise measurements it has been estimated that the squid giant axon contains about 60 K⁺ channels μm^{-2} (ref. 2), but this figure remains to be confirmed by other methods. Here I report experiments showing that specific and covalent labelling of tetraethylammonium (TEA) binding sites with a radioactive photoaffinity label can be achieved. 4-Azido-2-nitrobenzyltriethylammonium fluoroborate has been shown to block selectively, and after irradiation irreversibly, potassium conductance in the node of Ranvier of frog sciatic nerve³. I present here evidence that in crayfish unmyelinated nerve fibres, the label used reacts with a hydrophobic area at the mouth of the potassium channel postulated by Armstrong⁴.

Walking nerve from *Astacus leptodactylus* was cut into small pieces and 50 mg of tissue was homogenised in 0.2 ml Ringer's solution with a glass Micro-Homogeniser (Micro-Metric Instrument Company, USA). The homogenate was washed three times by centrifugation and resuspension to remove the soluble proteins. The washed membranes were incubated with the photoaffinity label (³H activity 100 mCi mmol⁻¹, synthesised by H. Kiefer, Basle) at final concentration as indicated in the legends to the Figures. After 10 min pre-incubation in the dark, irradiation was performed with an ultraviolet lamp (Sterisol, Quarzlampen GmbH, Hanau, Germany) mounted 5 cm above the sample. The irradiated sample was washed three times by centrifugation and resuspension to remove non-covalently bound photolabel. The labelled membranes were extracted overnight with 1% Triton X-100 in Ringer's solution containing 0.1 mM phenylmethylsulphonylfluoride and 0.02% sodium azide. After 30 min centrifugation at 40,000g the Triton extract was submitted to SDS-polyacrylamide gel electrophoresis⁵.

Figure 1a shows that apart from radioactive material not entering the 10% polyacrylamide gel, there is only one radioactive component migrating slightly slower than the tracking dye. None of the protein bands in the gel contains significant amounts of label. The residual membrane proteins which could not be extracted with Triton (Fig. 1b) were not labelled either. Figure 1c shows that analysis of a labelled membrane which does not contain voltage-dependent potassium channels, namely the postsynaptic membrane from *Torpedo californica* electric tissue. Here the radioactive band of Fig. 1a is missing; instead all the protein bands which have been shown to be part of the acetylcholine receptor complex are labelled. (This is in agreement with the affinity of the acetylcholine receptor for photolabels containing quaternary ammonium groups⁶) The three experiments of Fig. 1 indicate that the photolabel reacted selectively with a component typical for the excitable membrane of the crayfish nerve, presumably a

Fig. 1 SDS-polyacrylamide gel electrophoresis of crayfish nerve membranes labelled with the photoaffinity label 4-azido-2-nitrobenzyltriethylammonium fluoroborate. *a*, Absorbance (---) and radioactivity per mm gel slice of a 10% polyacrylamide gel. Walking nerve membranes of *Astacus leptodactylus* were labelled by 2-min irradiation at room temperature of an incubation mixture containing about 1 mg ml⁻¹ membrane protein and 0.5 mM tritiated photolabel in Ringer's solution. Electrophoresis (from left to right) was performed with a Triton X-100 extract of this membrane preparation containing 5 μg protein, at 8 mA per gel. The gels were stained with Coomassie blue. The main radioactive component migrated slightly slower than the tracking dye, the bulk of the lipids (visible as a white band) slightly faster. *b*, Absorbance and radioactivity of a gel of the membrane after Triton extraction. After centrifugation of the axon suspension in 1% Triton X-100 the Triton-insoluble pellet was dissolved in 1% SDS containing 10⁻³ M dithiothreitol. Electrophoresis as in *a*, with 5 μg protein on the gel. *c*, Control with a membrane not containing voltage-dependent potassium channels. Postsynaptic membrane fractions rich in acetylcholine receptor prepared from *Torpedo californica* electric tissue⁷ at a concentration of 0.2 mg ml⁻¹ in Ringer's solution were incubated with 0.5 mM photolabel and irradiated for 2 min. Electrophoresis with 10 μg of the labelled protein was the same as in *a* and *b*. Note that the main radioactive band of the upper gel is missing. Instead, the main proteins of the receptor membrane α - δ reacted with the label although not equally: the δ component incorporated only little radioactivity (as observed before⁸) again confirming the selectivity of the photoaffinity label.

tetraethylammonium (TEA) binding component of the potassium channel.

As further proof of this assumption two criteria of the specificity of a label for a given binding site were investigated: interaction with specific drugs and saturability. Figure 2 shows the concentration dependence of the ligand binding. Saturation was accomplished at an extrapolated incorporation of 12.5 pmol photolabel per μg protein extractable by Triton X-100 and from this result an attempt was made to estimate the density of binding sites in the axon membrane. From electron microscope pictures of a cross section of the nerve (performed by Ms Cahill in Professor Florey's laboratory) we estimated the axon surface area of 1 cm of the nerve. This amount of nerve incorporated 312 pmol of the label or 59×10^{-11} pmol μm^{-2} ; which represents 354 binding sites μm^{-2} . Size and number of fibres varies by orders of magnitude over the cross

Fig. 2 Concentration dependence of the incorporation of photolabel into crayfish nerve membranes. The ordinate refers to the main radioactive band in the SDS-polyacrylamide gel of membranes prepared, labelled and extracted with Triton X-100 as described. The inset shows the reciprocal plot of the data of the main figure. Extrapolation suggests saturation at 12.5 pmol label per μg protein in the Triton extract. Standardisation with the amount of extractable protein is not intended to suggest that the labelled molecule is a protein. The radioactive band in the gel in fact probably represents a lipid associated with proteins *in situ*.

section of the nerve and so the results from several fairly representative areas were averaged for the calculation. Taking parts of the nerve with small fibres, that is, with large axon surface area, the number of binding sites is about $220 \mu\text{m}^{-2}$. This still seems to be high but since it is preliminary, analogous experiments with squid giant axons are under way.

TEA-C9, the strong inactivator of potassium conductance investigated by Armstrong⁴, protects the membrane against incorporation of photolabel (Table 1). A larger protective effect cannot be expected because during 1 min irradiation the reversible ligand TEA-C9 competes with the covalently reacting photolabel. Treatment of the Triton X-100 extract before the SDS electrophoresis with phospholipase A₂ from hog pancreas (Boehringer, Mannheim, Germany) reduces by about 75% the recovery of radioactivity from the gel; phospholipase D, trypsin and chymotrypsin have no effect. The total radioactivity can be extracted from the membrane with chloroform-methanol 2:1. These results seem to indi-

Table 1 Effect of the TEA analogon TEA-C9 in which one of the ethyl groups is substituted by a nonyl residue

Photoaffinity label (mM)	TEA-C9 (mM)	Inhibition (%)
0.5	10	19
0.25	10	67

The reagent was supplied by E. Rojas, Norwich, England.

cate that the labelled molecule is a phospholipid or a small proteolipid. Armstrong has shown that substitution of one ethyl group of TEA by more hydrophobic residues increases its potency as inactivator of the potassium conductance. This is in agreement with a model of the channel that postulates a hydrophobic area at its mouth. The results presented here may indicate that the photoaffinity label reacted with the lipid rim of the funnel-like entry⁴ to the potassium channel.

The claim that the photolabel selectively reacted with components of the potassium channel is based on three observations: The saturation curve obtained with increasing label concentrations; the competition with the specific potassium conductance inactivator TEA-C9; and the electrophysiological experiments with the frog sciatic nerve³. This last is based on the assumption that the pharmacological properties with respect to TEA and its derivatives are similar in the crayfish axons used here and the frog sciatic nerve investigated previously³. These experiments suggest that photoaffinity labelling might be a valuable tool for the determination of ion channel densities and channel structure in various tissues.

I thank Ms Jutta Birsner and Mr Giampiero Bandini for technical assistance. Ms Grace Chapman introduced me to the preparation of the nervous tissue, and Professor Florey and Dr Walther supported me with helpful discussions. Pentylentetrazol and penicillin are selective antagonists of GABA-mediated post-synaptic inhibition in cultured mammalian neurones

PENTYLENETETRAZOL (PTZ) and penicillin (PCN) are potent convulsants commonly used to produce focal or generalised epileptiform discharges in the mammalian central nervous system¹. Investigations of the cellular basis for their convulsant effects have been performed in various vertebrate and invertebrate preparations with two basic hypotheses dominating the literature: (1) that the convulsant effect is

produced by pharmacological actions on synaptic transmissions to reduce inhibition²⁻⁸ and/or to enhance excitation⁹, or (2) that the convulsants directly enhance the excitability of neuronal membranes apart from effects on synaptic transmission¹⁰⁻¹⁶. We have studied the mechanism of their convulsant action in a mammalian tissue culture system and report here that both PTZ and PCN selectively antagonise post-synaptic responses to γ -aminobutyric acid (GABA), a putative inhibitory neurotransmitter¹⁷. The results presented here provide direct evidence derived from the mammalian nervous system that the convulsant action of PTZ and PCN may be due to a specific pharmacological action on GABA-mediated inhibitory synaptic transmission.

Mouse spinal cords were dissected from 12-14-d-old mouse embryos and mechanically dissociated; the cells were plated at a density of about 10^6 cells per 35-mm diameter dish and grown in tissue culture for at least 4 weeks before electrophysiological study¹⁸. Mature cultures at this age contain numerous well-differentiated neuronal cell types but in these experiments only the larger diameter (10-50 μ m) multipolar spinal cord (SC) nerve cells were studied. SC cells were penetrated under direct vision on a modified stage of an inverted phase contrast microscope with either 3 M KCl or 4 M K acetate microelectrodes (25-50 M Ω). Use of a conventional bridge circuit allowed simultaneous recording of membrane potential and injected current. All recordings were made in the normal growth medium (90% modified Eagle's medium/10% horse serum); MgCl₂ was added to a final concentration of 10 mM to suppress spontaneous synaptic activity and thus allowed a clearer examination of postsynaptic pharmacology. Glutamate (0.5 M pH 8), GABA (0.5 M pH 3.5), glycine (0.5 M pH 3.5), β -alanine (0.5 M pH 3.5), Na penicillin (0.3 M pH 5.6) (all Sigma) and PTZ (0.3 M pH 6) (K & K) were iontophoresed from high resistance (50-100 M Ω) theta glass micropipettes.

Both PTZ and PCN rapidly and reversibly antagonised the voltage response and conductance change evoked by iontophoresis of GABA without affecting responses to either glycine, β -alanine or glutamate (Fig. 1). The depression of the GABA response by concurrent iontophoresis of convulsant was observed on 25 SC cells with PCN and on

20 SC cells with PTZ, and in both cases the depression was dose dependent. The selectivity of either convulsant's antagonism of GABA responses has been observed on 20 cells examined with both GABA and either glycine, β -alanine or glutamate. Furthermore, PCN applied iontophoretically at currents which produced inhibition of the GABA response did not significantly alter resting membrane potential, input resistance, the inversion potential of the GABA response or the characteristics of the action potential (unpublished observations). Similar observations were made with PTZ except for a slight increase in input resistance noted at high currents. Thus, iontophoretically applied, both PCN and PTZ selectively depress GABA-mediated post synaptic responses on mammalian spinal neurons at doses which have no effect on other membrane properties.

Analysis of GABA dose-response curves obtained during control conditions and during coincident iontophoresis of PTZ or PCN suggests that the convulsants inhibit the GABA response competitively. In addition, the manifest selectivity of both convulsants for GABA also suggests that they both compete for GABA at the GABA receptor and not at the chloride conductance mechanism, as has been suggested previously⁷ for PCN. The finding that PTZ selectively blocks the GABA response in mammalian cultured neurones is in contrast to observations made in the frog spinal cord⁸ where PTZ antagonises the dorsal root potential and the action of GABA, β -alanine and taurine on primary afferent fibres with no ability to antagonise the hyperpolarising responses of these neutral amino acids on motoneurons. The results thus indicate that PTZ and PCN are GABA-specific antagonists in the mammalian central nervous system and support the hypothesis that part of their convulsant action is based on a selective blockade of GABA-mediated inhibition.

Fig. 1 PCN (A) and PTZ (B) selectively antagonise GABA-mediated postsynaptic responses in cultured mammalian neurones without affecting responses to β -alanine (BALA), glycine (GLY) or glutamate (GLU). All recordings were made using 3 M KCl micropipettes with the cell hyperpolarised to about -90 mV. In these conditions, the inversion potentials for all amino acid responses are more depolarised than -30 mV, and thus all responses shown are depolarising. The amino acids were iontophoresed with 50-ms pulses using micropipettes positioned close to PCN and PTZ pipettes at the neuronal surface. In each case shown, the GABA response was depressed by PCN or PTZ with no change occurring in the other amino acid responses. The 1-s time bar is applicable to all responses except for the GLU and GABA responses in a. Con, control traces.

Reactivation of murine cytomegalovirus by cyclophosphamide

THE high prevalence of cytomegalovirus (CMV) infection in transplant recipients is well known but our understanding of the risk factors involved is incomplete. It is thought that the role of immunosuppression is probably paramount. In a series of rheumatologic patients followed prospectively

Table 1 Reactivation of MCMV in DBA/2 mice by cyclophosphamide

	No. of cyclophosphamide injections			
	0	1	2	3
Salivary gland	0/10*	0/4	11/13	8/8
Kidney	0/10	0/4	3/13	0/8
Lung	0/10	0/4	2/13	0/8
Spleen	0/10	0/4	0/13	0/8
Liver	0/10	0/4	0/13	0/8

MCMV was assayed by plaque formation on monolayers of mouse embryo cell cultures under an overlay containing 0.8% gum tragacanth⁴. Virus titres in the salivary gland ranged from 2.18 to 3.54 log₁₀ PFU per 10 mg of tissue.

*No. of animals with virus in organ/total.

after initiation of cyclophosphamide therapy, a significant proportion (43%) developed CMV infection as evidenced by viruria and serologic response¹. Since most of these infections were seen in initially seropositive patients, we believe that they represent reactivations of latent (herein defined as an infection in which no virus can be detected by standard plaque assays) or inapparent infection. Presumably, reactivation by immunosuppression also occurs in transplant recipients. Another risk factor for CMV infection in renal transplant recipients is the transfer of kidneys from donors seropositive for CMV into seronegative recipients^{2,3}. We are using the mouse cytomegalovirus (MCMV) model for better understanding of the factors involved in latency and reactivation of this group of herpes-like viruses and have shown that allografting will enhance chronic MCMV infection in the recipients⁴. We present here further observations on the mouse model, showing that latent MCMV infection can be reactivated by treatment with cyclophosphamide and that the transfer of latently infected spleen cells can lead to infections in recipients. We also show a role for immunosuppression in the latter situation.

Latent infections were developed by injection of 5–6-week-old DBA/2 inbred male mice (Jackson Labs) with 2×10^5 plaque-forming units (PFU) of MCMV, Smith Strain, intraperitoneally (i.p.). Free virus was no longer detectable in the spleen by 6 weeks after infection. Lungs, liver, kidney and salivary glands were clear by 16 weeks.

Animals that had been infected 20–24 weeks previously were treated with one, two and three doses of cyclophosphamide (150 mg per kg body weight) 5–6 d apart. Their organs were removed, homogenised as 10% suspensions in cell culture medium, clarified by centrifugation and titrated 2 weeks after the last dose (Table 1). Untreated control mice and mice which received only one injection of cyclophosphamide had no detectable free virus in any of the organs tested. On the other hand, 11 out of 13 mice receiving two doses of the drug and all mice treated after three doses reactivated CMV in the salivary gland. The total number of mice in which MCMV was reactivated is

the same as the number of salivary glands positive (Table 1), since MCMV was not found in other organs of mice with MCMV-negative salivary glands. The finding of virus almost exclusively in the salivary gland does not necessarily mean that it is the site of reactivation, as virus in any part of the animal might migrate to the salivary gland, the favoured site of virus replication.

Although investigators could not reactivate herpes simplex virus infections in sensory ganglia of mice using cyclophosphamide⁵, the results presented in Table 1 indicate that cyclophosphamide treatment can reactivate inapparent or latent CMV infections. There is, however, a small but important possibility that the results were produced by amplification of a smoldering but undetected lytic infection. Indeed this possibility is virtually impossible to eliminate.

In an attempt to establish the existence of a transferable, latent CMV infection, spleen cells from DBA/2 mice infected 8–12 weeks previously were used as donors in spleen cell transfer experiments. Recipient DBA/2 and C57BL/10 mice aged 6–10 weeks were treated with a single dose of cyclophosphamide (150 mg per kg) 48 h before injection with 10⁶ whole or sonically disrupted spleen cells. Four weeks later, salivary glands from normal and immunosuppressed mice were removed and titrated (Table 2). Transfer of latently infected DBA/2 spleen cells into syngeneic hosts resulted in frequent reactivation in similar proportions of both normal and immunosuppressed animals. Transfer of the same cells into allogeneic C57BL/10 mice, however, resulted in infection in a significantly greater number of treated than untreated recipients ($P < 0.05$)⁶. Free virus was not detected by titration of disrupted donor spleen cells or by injection of 10⁶ sonically disrupted cells into immunosuppressed DBA/2 mice. As a control, we performed 'reconstruction' experiments by adding free virus to suspensions of spleen cells before disruption. Recovery of the virus was >80% using cells derived from either normal or latently-infected animals, suggesting that lytic virus was not inactivated by cell debris or sonication.

These results demonstrate that MCMV may produce latent infections in spleen cells and that this latent infection can be reactivated in other animals by cell transfer. Additionally, in allogeneic recipients, infections due to reactivation of the donated spleen cells were more frequent in cyclophosphamide treated mice than in untreated animals.

The reactivation of latent MCMV by cyclophosphamide provides supportive experimental evidence of the postulated role of immunosuppression in CMV infection of transplant recipients and other immunosuppressed patients^{1,2,7}.

The apparent reactivation of latently-infected spleen cells in non-immune recipients closely resembles the situation seen in kidney transplant recipients. The enhancing effect of cyclophosphamide in allogeneic recipients was probably due to the suppression of rejection of latently-infected transplanted cells, and survival of such cells seems to be the most important factor in determining the frequency of reactivation in this system. A direct effect of cyclo-

The D2BAL-10 MuLV, isolated from a dimethyl(α)-benzanthracene-induced, transplantable DBA/2 leukaemia, was injected into newborn BALB/c mice. When they were 36 d old p30 was determined by radioimmunoassay* in the blood of individual mice (Fig. 1). In eight of 13 mice injected with virus we found significantly increased levels of blood p30, ranging from 760 to 1,200 ng ml⁻¹, whereas

One of the control animals with a low p30 concentration in the blood died after 192 d with enlarged lymph nodes and splenomegaly, possibly due to leukaemia. The remaining 12 control animals were alive without signs of disease

Fig. 1 Newborn BALB/c mice were injected with D2BAL-10 MuLV. Concentration of p30 at 36 d in blood from mice injected with virus (●), and from control mice receiving only buffer + DEAE-dextran (○) is shown in relation to later mortality. A cell-free extract, prepared from D2BAL-10 ascites cells (13 passages), was added to monolayer cultures of SC-1⁷ murine cells. Forty-eight-h collections of MuLV were concentrated 400-fold by producing a pellet of virus from the supernatant medium and resuspending in TEN buffer (20 mM Tris-HCl, 1 mM EDTA, 100 mM NaCl, pH 7.6) with p30 at about 0.4 mg ml⁻¹. DEAE-dextran⁶ was added to a concentration of 25 µg ml⁻¹. Each of 13 newborn (less than 24 h old) BALB/cABoM-Fib mice received 50 µl of the virus suspension subcutaneously on the back, and 13 newborn BALB/c received 50 µl of TEN buffer with DEAE-dextran (25 µg ml⁻¹). At 36 d a 25-µl sample of blood from each mouse was collected in one tenth volume of 100 mM NaEDTA, pH 6.5. The proteins were solubilised by addition of Triton X-100 to a final concentration of 0.4% followed by freezing and thawing. The radioimmunoassay mixture⁸ contained 0.5 ng of ¹²⁵I-Rauscher-MuLV p30, 12 nl of rabbit anti-FeLV, 1 µl of nonimmune rabbit serum and 10 µl of blood, or a standard dilution of Rauscher-MuLV p30, in a total of 120 µl of TENG/BSA (TEN buffer containing 0.2% Triton X-100, 0.1% NaN₃ and bovine serum albumin (5 mg ml⁻¹)). The antibody-bound radioactivity was precipitated by pig immunoglobulin against rabbit IgG (Dakopatts, Denmark), collected on membrane filters, washed and counted.

after 13 months. They had normal concentrations of blood p30 ($<50 \text{ ng ml}^{-1}$) after 200 d.

These results suggest that the D2BAL-10 MuLV isolated from a long-transplanted, chemically-induced DBA/2 leukaemia is oncogenic in BALB/c mice. It is also obvious that infection of newborn mice with the virus leads to high concentrations of the core protein, p30, in the blood within the first 5 weeks of life in most cases. The increased concentrations of p30 in the blood probably represent replication of the inoculated MuLV in the animals. Finally, there seems to be a significant correlation between early high p30 concentrations in the blood of otherwise healthy animals and the subsequent development of leukaemia. The results agree with the observation that quantification of p30 in the blood identifies among inbred strains of mice, a group which is at high risk of developing leukaemia⁶.

We thank Drs Mette Strand and Thomas August for antiserum, Drs Jack Gruber and George Todaro for help in obtaining Rauscher-MuLV and Dr Walter A. Nelson-Ress for help in obtaining SC-1 cells. Histone content of germinating pea embryo chromatin decreases as DNA replicates

MODIFICATIONS in the expression of genetic information in eukaryotes are probably controlled by changes in the proteins associated with chromatin¹. Unfortunately, in most of the differentiating systems which have been studied these changes are barely detectable, so that we do not know either which changes occur or when they occur. As a part of a more general study of the molecular developmental biology of seed germination we have investigated changes in chromatin of germinating pea embryo axes. Some particularly interesting features of this biological system make it useful for studying developmental changes in chromatin structure. First, it is quite easy to obtain large numbers of homogeneous seeds. Second, germination constitutes a switch from a dormant, arrested state to a new developmental programme. It is thus possible to study the sequence of molecular events which underlie the transition from a completely inactive genome to an active one. Third, this reactivation of the genome is accompanied by two waves of synchronous mitoses which can be considered as temporal markers. Finally, the germinating embryo constitutes a set of differentiating tissues. To our knowledge, no animal system shares all these features together. The results which are described in the following sections demonstrate that a considerable loss of histone per DNA unit is associated with this reactivation of the

genome during germination and that most of these changes take place as DNA replicates.

Histones from pea embryo chromatin were prepared as described previously; these had been characterised using polyacrylamide gel electrophoresis, electrofocusing and amino acid composition^{2,3}. Briefly, chromatin was prepared from a nuclei-enriched pellet. Most of the contaminating material was removed by several washings and the chromatin was further purified by dissociation in 2 M NaCl followed by gentle reassociation in 0.15 M NaCl. To prevent protease activity, sodium thiosulphate was included in all buffers, and all operations were carried out at 4 °C. That no degradation occurs is indicated by the SDS-polyacrylamide gel electrophoretogram shown in Fig. 1. Molecular weights of the individual histones were in accordance with previously published values^{1,4}.

We first determined the total histone/DNA ratio in

Fig. 1 SDS-polyacrylamide gel electrophoresis pattern of dry pea embryo histones. Chromatin was extracted by homogenisation of embryos in 0.05 M Tris buffer pH 8.0, containing 0.25 M sucrose, 0.001 M MgCl_2 , 0.01 M β -mercaptoethanol and 0.05 M sodium thiosulphate. After filtration of the homogenate through Miracloth, a nuclei-enriched pellet was obtained by centrifugation at 8,000g for 20 min. The pellet was washed three times, twice with the above buffer lacking sucrose and magnesium and finally with 0.01 M Tris buffer, pH 8.0, containing 0.002 M β -mercaptoethanol and 0.05 M sodium thiosulphate. The crude chromatin pellet was then dissociated in 0.01 M Tris buffer, pH 8.0, containing 2 M NaCl and 0.05 M sodium thiosulphate, and gently reassociated by dialysis against the same buffer lacking NaCl, to a final concentration of 0.15 M NaCl. Total histones were extracted by stirring twice with 0.25 N HCl for 2 h and precipitated with eight volumes of acetone at -20 °C for 24 h. After centrifugation, the histone pellet was washed successively with acetone and ether and air dried. Histones were analysed by electrophoresis on 12.5% acrylamide gels containing SDS prepared by the method of Laemmli and Favre⁵. Electrophoresis was at 3 mA per gel for 6 h, with bromophenol blue as tracking dye. Gels were stained with Coomassie Brilliant Blue R and scanned at 620 nm with a Chromoscan (Joyce Loebel) apparatus. Molecular weights were estimated by the procedure of Weber and Osborne⁶.

Fig. 2 Changes in DNA amount and in histone/DNA ratio during germination. DNA was extracted by the phenol-chloroform method of Marmur⁷, from embryos germinated for the required period, and assayed spectrophotometrically (●). Chromatin, prepared as described in Fig. 1, was divided into two parts: one for the DNA estimation by the above method, the other for histone extraction (as described in Fig. 1) and estimation by the Lowry method⁹. The histone/DNA ratio of chromatin was calculated (▲).

purified chromatin and examined its variation as a function of germination time. Figure 2 shows the changes in embryo DNA content and in the total histone/DNA ratio. DNA content increases in two steps corresponding to the two waves of mitosis. This has been confirmed by ¹⁴C-thymidine incorporation and cytological observation of numerous mitoses. The histone/DNA ratio curve demonstrates that the histone content of purified chromatin decreases as the germination proceeds. Strikingly, decreases in the ratio are synchronous with DNA synthesis, providing clear evidence that major changes in chromatin take place at the time of DNA replication. Note also that the large excess histone in the dry embryo is most likely accounted for by actual DNA-bound histones than by a storage form, since no free histone can be detected either in the different washings of

Fig. 3 Molar percentage of each histone as a function of germination time. Histones were isolated separately by the differential extraction procedure (method 2) of Johns⁸ and assayed by the method of Lowry⁹. In our hands, this yields a fraction corresponding to H2B partially contaminated by H2A. The percentage of contamination was evaluated by electrophoresis and the values corrected. Using the molecular weights as determined in Fig. 1, the molar percentage of each histone was calculated. O, H2A; □, H2B; ▲, H3; ●, H4.

the crude chromatin or in the cytoplasm, and since chromatin purified through a sucrose gradient yields the same high histone/DNA ratio (our unpublished results).

We then asked whether each individual histone behaves in the same way or not. Since an accurate quantitation of each individual histone is difficult to obtain by gel electrophoresis, due to differential dye binding, we fractionated the total histone preparation by a selective extraction procedure^{3,8}. Each fraction was checked for purity by gel electrophoresis and assayed by the Lowry method⁹. Using the molecular weights, we calculated the molar percentage of each individual histone and plotted them against time of germination. The data presented in Fig. 3 clearly demonstrate that four of the histones (H2A, H2B, H3 and H4) remain in equimolar proportions although their total amount per DNA unit decreased. This suggests that they remain associated together in a nucleosome-like structure at every stage of germination, including the waves of mitosis. On the other hand, H1 behaved independently. As the germination proceeded, the relative proportion of H1 decreased in steps which, again, showed a remarkable coincidence with DNA doublings.

A direct implication of these observations is that accessibility of DNA in chromatin to endonucleases should increase during the period considered. Chromatin corre-

Fig. 4 Digestion of chromatin by DNase II. Mild digestion of chromatin from dry (a and c) and 72-h-old (b and d) embryos was carried out as described previously¹⁰. Each assay contained 5 A_{260} units of chromatin ml^{-1} , and DNase II at a concentration of 6.4 μg DNase per A_{260} unit. Aliquots were taken at various times to test for the production of TCA-soluble material (measured by absorbance of the supernatant at 260 nm after centrifugation at 27,000g and 4°C for 15 min). The kinetic studies of the hydrolysis (a, b) revealed a rapid initial digestion followed by a slower one. Sucrose gradient analyses (c, d) were carried out during this slower process with chromatin digested for 4 h. An aliquot (1 ml) of each digest was layered on to a 5–20% sucrose gradient. Centrifugation was for 10 h at 40,000 r.p.m. and 4°C in a Ti SW 41 Beckman Rotor. Gradients were eluted with an ISCO apparatus.

sponding to different stages of germination was hydrolysed with low concentrations of DNase II, and the digests were analysed on sucrose gradients¹⁰. Figure 4 shows two extreme situations, corresponding to dry and 72-h-old embryos. The time courses of the digestions are shown in the top panels. The profiles are similar to those obtained by other workers^{10,11}. The slowest sedimenting particle can be considered as the nucleosome monomer since it exhibits the following properties: it contains all histones except H1, a short DNA molecule homogeneous in size, and has a buoyant density in CsCl of 1.48 g cm^{-3} . Digestion of germinated embryo chromatin (Fig. 4d) yields a larger amount of hydrolysed material than dry embryos (Fig. 4c). These data have been extended to the overall period and the amount of hydrolysed material plotted against germination time (Fig. 5). Obviously the accessibility of DNA increases during germination and the changes correlate with a reduction in the histone/DNA ratio.

Our results provide original information on changes in chromatin structure in the course of a developmental process. They demonstrate that less and less histone is bound to DNA as the genome is re-activated and transcribed. Particularly relevant to the relaxation of the genome was the progressive disappearance of histone H1, the latter being assumed to help in condensing chromatin¹². Note that the level of H1 increased dramatically during seed maturation and thus probably contributes largely to the functional inactivation of the seed genome¹³.

Our results are also in accordance with the observation that H1 is absent or very much reduced in actively transcribed chromatin from animal cells¹⁰. The other four histones remain in equimolar amount and the nucleosome structure is conserved during the overall germination period. As a consequence, the decrease in the histone/DNA ratio and the increase in the DNA accessibility in chromatin can be best interpreted as a decrease in the nucleosome number along the DNA fibre. These changes are correlated

with active transcription of numerous genes¹⁴ and accumulation of non-histone chromosomal proteins¹⁵. This suggests that although nucleosomes are clearly associated with actively transcribed genes¹⁶⁻¹⁹, nucleosome density along the DNA fibre might be a crucial parameter in controlling gene expression. Such a dramatic change can probably be demonstrated only when cell division is required for differentiation and when a large number of genes have to be switched on or off. For example, recent data²⁰ indicate that the differentiation of the avian red blood cell is accompanied by a progressive packaging of more and more histones along the DNA until it is almost completely inactivated. We describe here the reverse situation, in that a repressed genome is reactivated.

In addition, we show that most of the changes involving histones take place at the time of DNA synthesis. This observation has been possible only because most of the cells of the embryo axis replicate their DNA twice with relatively good synchronisation. Note that our results bring direct evidence that when cells divide in a developing system the DNA-bound stock of histone and the chromatin structure and composition are not necessarily identical in mother and daughter cells. This probably constitutes part of the mechanism which allows new sets of genes to be switched on, being a key element in controlling development and cell differentiation.

Nature Index and Binders

The complete **Index** for 1976 is available, price £2.50. Copies of the 1975 index are still on sale, price £3.00. **Binders** for the journal are also available at £8.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

matters arising

Circular superhelical DNA

BRADY *et al.*¹ have presented an excellent X-ray diffraction study of circular superhelical DNA and have shown that the native superhelix of circular DNA from PM2 bacteriophage produces two maxima at angles corresponding to Bragg spacings of 337 and 2,100 Å. We feel that the interpretation given by them for these maxima could be improved in several respects:

(1) The 337 Å maximum is due to superhelical formation by two DNA double helices. Brady *et al.*¹ have neglected the double nature of the superhelix so that their derivation of the

Fig. 1 Helical parameters (p , pitch; r , radius, in Å) for double superhelices which have a scattering maximum at 337 Å. The continuous line has been calculated as described in ref. 3. DNA was simulated by a cylinder of 20 Å diameter. The dashed line is the approximate equation (1) given in the text.

helical parameters is not correct. The first maximum observed will occur in the second layer line. This maximum is approximately related to the helical parameters through the relationship derived directly from the equation for ordered helices²

$$(1/d_{\text{obs}})^2 = (2/p)^2 + (0.487/r)^2 \quad (1)$$

A more accurate relationship can be obtained by numerical calculation from the scattering equation of disordered double helices³. Figure 1 shows that equation (1) describes with sufficient accuracy the relationship between the helical parameters p and r and the position d_{obs} of the first scattering

Fig. 2 A comparison of the experimental scattering curve of superhelical PM2 DNA (redrawn from Brady *et al.*¹) and three theoretical curves calculated by the method of Puigjaner and Subirana³: a , $p = 3,300$ Å, $r = 165$ Å; b , $p = 1,440$ Å, $r = 180$ Å; c , $p = 1,020$ Å, $r = 204$ Å. A very shallow maximum is found for large values of the pitch (curve a), since in this case the double superhelix approaches the behaviour of two parallel DNA molecules placed at a mutual distance of about 337 Å. On the other hand, for low values of the pitch ($p < 800$ Å, not shown) the double superhelix approaches a hollow cylinder and new maxima appear, which obscure the maximum due to the superhelical nature of the molecule. Taking into account that the experimental curve has neither been desmeared, nor the background corrected, the dimensions of the superhelix should fall between the values given for the b and c curves.

maximum. In order to determine the actual dimensions of the superhelix, use can be made of the fact that the sharpness of the maximum varies with p and r , as shown in Fig. 2. Unfortunately the experimental limitations¹ do not warrant an exact adjustment of the experimental and theoretical curves, but it can be concluded from such comparison that the radius of the superhelix lies in the range 180–200 Å, with a corresponding pitch in the range 1,400–1,000 Å, dimensions which are about twice those predicted by Brady *et al.*¹

(2) The peak at 2,100 Å has been attributed by Brady *et al.*¹ to a second-order superhelix. To determine its dimensions, Brady *et al.*¹ used an approximate formula which deviates significantly from the calculated values for single superhelices, as shown in Fig. 3. This is due to the fact that scattering in the equatorial plane interfaces strongly with the position of the first layer line peak. Furthermore, the 1,23 factor used by

these authors does not seem to be suitable to correct for the random orientation of helices. From the values shown in Fig. 3, and taking into account the shallow shape of the experimental maximum, it can be concluded that the secondary superhelix has a radius of 650 ± 150 Å and a pitch of $2,800 \pm 100$ Å. The pitch can be determined rather accurately, due to the maximum of the theoretical curve shown in Fig. 3. These values indicate that there are three to four second-order turns per molecule.

Fig. 3 Helical parameters (p = pitch, r = radius, in Å) for single superhelices which have a scattering maximum at 2,100 Å. The continuous line has been redrawn from the results presented elsewhere (Fig. 3 in ref. 3). The dashed line is the equation (1) used by Brady *et al.*¹. Calculation³ shows that the continuous line cannot be extended towards both ends, since the superhelical maximum is then obscured by diffraction in the equatorial plane of the superhelix. The sharpness of the maximum increases from left to right.

We should also mention, however, that other interpretations for the 2,100-Å peak are possible. It could be due, for example, to formation of a loop, such as a double superhelix, with the distance between the two strands close to 2,100 Å.

BRADY *et al.*¹ have reported that the X-ray scattering pattern from superhelical PM2 DNA differs from that of its non-superhelical counterpart and interpret their results in terms of unusual tertiary conformational features of the molecule. In so doing they ignore the well documented chemical^{2,3} and enzymological^{4,5} evidence that the secondary structure of superhelical DNA is abnormal and fail to attempt any estimate of the quantitative effect that this may have on their experimental results. In addition, they have ignored the evidence from electron microscopy and light scattering which supports a branched structure for all superhelical DNA molecules with the regions of secondary structure variations situated at the end of the branches^{6,7}. As PM2 DNA possesses between four² and eight³ of such regions the concept of three high-order superhelices distributed over the entire molecule must be equated with there being less than one such turn per branch.

Down's syndrome in Kerala

KOCHUPILLAI *et al.*¹ reported an abnormally high incidence of Down's syndrome in an area of high background radiation in coastal Kerala. They stated that the radiation exposure of their study group is 1,500–3,000 mrad yr⁻¹. But on the basis of a dosimetric survey² only about 11% of the females in their study received doses in the range of 1,100–2,000 mrad yr⁻¹ and 2.8% received more than 2,000 mrad yr⁻¹. This is due to non-homogeneous distribution of monazite-containing beach sands in the region.

Kochupillai *et al.* observed a frequency of cases of 1 : 1,076 in the study group. Comparison with any other published value is valid if the age structures of the two populations are similar. The infant mortality in this region is about 200 per thousand births³ and is independent of the high background radiation. Furthermore, in most other surveys only 4% of all births have been to females 40 yr old

and above. The data of Kochupillai *et al.* show about 20% of females were in this age group, which incidentally carries the highest risk of bearing children with Down's syndrome. Although in Sweden and Germany 27–29% of the population are in the age group 0–19 yr, in India more than 52% are in this age group³. The greater frequency of Down's syndrome in the study group of Kochupillai *et al.* than in those reported from other countries in ref. 1, could be explained solely in the differences in population structures.

Kochupillai *et al.* say: "Most striking is the higher frequency of cases of Down's syndrome born to mothers aged 30–39 yr (Table 3). This figure of 1 : 81 can be compared with 1 : 880 and 1 : 290 for maternal ages of 30–34 yr and 35–39 yr, respectively, calculated by Penrose and Smith⁷". But the ratio of 1 : 81 relates to the number of cases of Down's syndrome per female in the age group 30–39 yr, and the figures of Penrose and Smith⁷ are for frequencies among all births in these age groups. These are not comparable. Kochupillai *et al.* have demonstrated only that mothers in the age group 30–39 yr run a risk 10 times greater than those in the younger age group, which agrees with other evidence of increasing risk with advancing maternal age. They make no comment as to why this risk is about three times lower in mothers in the age group 40–49 yr. If high background radiation is involved, an even greater risk would be expected in this group than in comparable age groups of the general population. The age-specific risk increases almost exponentially from 1 in 290 at 35 yr to 1 in 46 in mothers aged 45 yr and older⁴.

The incidence of Down's syndrome at birth varies from 1 : 520 to 1 : 873 based on nine surveys⁴, with an average of 1 : 663 or 1.507 per 1,000 births for all age groups. Frequencies at birth of around 1 : 800 have been reported for several population groups in India⁵ which experienced normal background radiation. Lejeune⁶ compiled reports which demonstrated no difference between Oriental and Caucasian populations.

Based on values of family size (6.2), the number of females (2,213) in the study population (12,918), an infant mortality rate of 200 per thousand births and a mortality of 60 per 1,000 births in the age group 1–20 yr, a total of 11,500 births is estimated in the study population of Kochupillai *et al.* Using a mean value reported by Penrose and Smith⁷ of 1.507 per 1,000 births, about 17 cases of Down's syndrome would be expected at birth. On the basis of data for the maternal age at birth reported by Verma⁸ and Collmann and Stoller⁴, I have made a more

rigorous calculation, by redistributing the total births estimated into various age groups, on the basis of the number of females in each age group in Table 3 of ref. 1. This gives about 20 cases of Down's syndrome per 11,500 births. (The value should be even higher in this case because 20% of mothers were aged 40–49 yr, unlike any other populations studied.) This figure when corrected for mortality rate⁷ would leave 9 or 10 cases in the population at the time of the study.

Kochupillai *et al.* observed 12 surviving cases of Down's syndrome. The differences between expected and observed are not significant. On the same basis, one would estimate three surviving cases in their control population but none were observed. The differences are not significant. Although it is difficult to explain this, it could have arisen because of the smaller sample size used for the control population as against the study group, and the possible association of a major cardiovascular defect in these cases.

KOCHUPILLAI *et al.*¹ reported that the prevalence of mental retardation of genetic origin was four times higher than normal in an area of high background radiation in coastal Kerala. As this background radiation is less than the limit of 5 rem yr⁻¹ recommended for registered radiation workers by the International Commission on Radiological Protection in 1965, this might cause anxiety both to those exposed and to those responsible for their welfare. We therefore wish to point out two reasons why the data are hardly sufficient to imply that the likely risks are so great.

First, 'severe mental retardation' is classified as a 'genetic abnormality'. Other data make it unlikely that more than a small proportion of such cases —of which mongolism (Down's syndrome) is the commonest—are due to any simple excess, deficiency or disturbance of the hereditary material.

Second, an area selected because mongolism was known to be common

was compared with an area in which no case was found in almost 6,000 persons, although one case would be expected in about 700 births.

The only firm data presented show that there were nine cases of mongolism born to 729 women aged 30–39 yr when about two would be expected—and two were born to women 40–49 yr old when about four would be expected. That is, 11 were observed, and, assuming no variation in racial incidence, about six were expected, making possible a very imprecise estimate of perhaps a doubling, perhaps more, but perhaps no increase.

VERMA *et al.* REPLY—The differences in the age composition of the population in India and western countries, which are likely to affect the frequency of Down's syndrome are relatively small (Table 1). Infant and childhood mortality in India is about six times higher than in western countries¹. The mortality of Down's syndrome is expected to be substantially higher than in the general population. We believe therefore that the difference observed in the population frequency of Down's syndrome between the monazite area of Kerala and other countries² is not an artefact due to lack of standardisation for age structure.

We realise that our comparison of the number of cases of Down's syndrome born to women of specified ages with the frequency at birth may not be entirely valid³. Similarly, Sundaram's comparison of 4% of all births to females 40 yr old and above in other surveys with 20% of females in this age group is incorrect. The percentage of women 40–49 yr-old is less in Kerala than in western countries (Table 1).

Sundaram concedes that we demonstrated a ten times higher risk in women 30–39 yr old than in younger

women. This is more than twice the usually reported risk^{4,5}. The risk of Down's syndrome births in the 40–49-yr-old age group is no less than that in the 30–39-yr-old age group if the difference in age-specific fertility (about 56 and 186 per female in the two groups respectively)¹ is remembered.

Calculating the expected number of cases of Down's syndrome in the study population, Sundaram has incorrectly equated the mortality of Down's syndrome with the usual childhood mortality. It is more appropriate to estimate the rate at birth, starting with the observed number of cases: Down's syndrome patients, 12; less than 5 yr, 5; 5–10 yr, 4; more than 10 yr (average age 8.5 yr), 3. Assuming life table survival rates in cases of Down's syndrome in Kerala at 5, 10 and 20 yr as 40, 35 and 30% compared with Collman and Stoller's figures of 49.4, 46.2 and 38%, respectively⁶ (because of the substantially higher mortality in Kerala), the 12 observed cases would be survivors of 33 liveborn cases of Down's syndrome. Accepting Sundaram's estimate of 11,500 births, the frequency of Down's syndrome would be 2.8 per 1,000 births. This can be compared with a frequency per 1,000 births of 1.5 in the world⁴, 1.2 for an all-India series⁷ (excluding Madras), and 0.8 for Trivandrum, Kerala with normal background radiation (six cases of Down's syndrome among 7,167 births in 1976; personal communication from Saguna Bai).

With respect to the dose of radiation in the monazite belt, we have quoted only published figures^{8–10}. The area surveyed is recognised to have a peak level of radiation. Sundaram's group¹¹ has reported that 80.3% of households in this area recorded radiation exposure greater than 500 mrad yr⁻¹. Almost 27% of households had radiation exposure of 1,000–2,000 mrad yr⁻¹ (Fig. 5 of ref. 11). The dosimetric profile of individuals totally employed in this area is closely similar to the household exposure profile¹¹. With regard to the point raised by Edwards and Harnden, these doses exceed the safe genetic dose recommended by the ICRP for individuals (5 rem yr⁻¹) and for the general population (5 rem per generation but excluding natural background

and medical radiation)¹². The Advisory Committee on Biological Effects of Ionising Radiation sets the limit for the general population at 10 R before the mean age of reproduction of 30 yr (ref. 13).

Edwards and Harnden question our classifying 'severe mental retardation' as a genetic abnormality. This group comprised Noonan syndrome, primary microcephaly, mental retardation associated with craniofacial abnormalities and congenital blindness, and familial cases of mental retardation. No environmental factors were operative in these cases and we think it is reasonable to consider them to be genetic in origin.

The study area was not "selected because mongolism was known to be common". The area was surveyed because it has a high background radiation and a possible relationship with thyroid disease was being investigated¹⁴.

Virus particles in marmoset hepatitis

SERUM from marmosets infected with the GB hepatitis agent has been reported (Almeida *et al.*¹) to contain aggregates of particles, 20–22 nm in diameter, and it was suggested that these particles may be the aetiological agent of GB hepatitis. Dienstag *et al.*² subsequently described the occurrence of 34–36-nm particles in homogenates of livers from marmosets infected with

Table 1 Age structure of population of females

Age group (yr)	Kerala ^{1,4} Study	Kerala ^{1,4} Control	India* 1961	Australia 1965	UK* 1966	Denmark* 1964

Figures are percentages.

*Figures from ref. 15.

Fig. 1 *a*, 22-nm particles present in marmoset serum. These particles are apparently coated with antibody ($\times 168,540$). *b*, 22-24 nm particles found in marmoset faeces ($\times 168,540$).

the GB agent, but antibody to these particles could not be detected in convalescent serum from the patient (GB) himself. Findings from marmoset transmission studies in this laboratory support the suggestion that the small serum particles described by Almeida may be aetiologically associated with hepatitis in marmosets.

Serum from cotton top marmosets (*S.oedipus oedipomidas*) which had been infected with the Berlin agent which is antigenically related to GB contained small aggregates of round virus-like particles approximately 22 nm in diameter (Fig. 1*a*). These particles seemed to be heavily coated with antibody. Since this serum pool is highly infectious for marmosets presumably free virus particles exist, but electron microscopy is not a sufficiently sensitive technique to be able to detect these.

Similar 22-24-nm round virus-like particles were transiently excreted in the marmoset faeces. Particles were not found in specimens collected on the seventh and twelfth day after inoculation, but a stool specimen collected from one animal on the tenth day contained both full and empty particles (Fig. 1*b*). These particles did not occur in aggregates and there did not seem to be any antibody on them. Levels of serum transaminases were first found to be significantly raised in the serum sample collected on the eleventh day.

The occurrence of 20-24-nm particles in serum of marmosets infected with both the GB and Berlin hepatitis agents, and the transient excretion of similar particles in faeces at the time when levels of serum transaminases were elevated, suggests that these small

virus-like particles may have a significant role in the development of Berlin and GB hepatitis in marmosets.

Marmosets infected with the GB and Berlin agents did not develop antibody to the parvovirus-like antigen found in human sera by Cossart³.

HAZEL APPLETON

³ Cossart, Y. E., Field, A. M., Cant, B. & Widdows, D. *Lancet* i, 72-73 (1975).

DIENSTAG REPLIES,—Appleton has demonstrated 22-nm virus-like particles in serum from *S. oedipus* marmosets infected with the Berlin agent, antigenically related to the GB agent¹. Like those in the report by Almeida

as presumed by Appleton, is highly unlikely. Whether these antibody-coated particles have been sought in non-infectious serum (pre-inoculation, convalescent, and/or normal marmoset serum) is not detailed in Dr Appleton's communication. Even if these antibody-coated particles cannot be detected in normal marmoset serum, as Almeida *et al.*² reported, conclusions about the aetiologic role of these particles are unwarranted, for the same reasons we pointed out in our letter⁴.

Regarding the detection of 22-24-nm particles in stool of one infected marmoset on day 10 but not day 7 or 12 after inoculation, the obvious questions are (1) whether pre-inoculation and convalescent stools were also examined, and (2) whether these particles can be aggregated by convalescent but not pre-inoculation serum from Berlin agent-infected marmosets. In our laboratory,

Fig. 1 Electron micrograph of 22-nm particles in the stool of a *S. mystax* marmoset. Such particles appear in normal marmoset stools as well as in stools of marmosets infected with hepatitis A virus and bear no serologic relationship to any known infection. (2% phosphotungstic acid negative stain) ($\times 132,000$).

*et al.*², the particles shown are heavily coated with antibody. Such a dense halo of antibody molecules and the large interparticle distance are characteristic of extreme antibody excess, rather than antigen excess³; therefore, the presence of antibody-free particles,

we have detected morphologically identical 22-nm particles (Fig. 1) in normal marmoset stools, in pre-inoculation, acute illness, and convalescent stools from marmosets infected with hepatitis A virus. These ubiquitous particles bear no serological relationship to any known illness and are easily distinguished from 27-nm hepatitis A antigen particles by immune electron microscopy⁵.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

reviews

White beard through the looking glass

Richard Dawkins

Behind the Mirror: A Search for a Natural History of Human Knowledge. By Konrad Lorenz. Pp. 261 (Methuen: London, 1977.) £4.90.

A PURELY PERSONAL PREJUDICE leads me to appreciate a book more if I am told, at the outset, what it is the author hopes to teach me. In place of the introductory chapter which might have served this purpose, *Behind the Mirror* begins with 'Epistemological Prolegomena'—long on Kant but, apart from a cryptic last sentence, short on statements of intention. In the final chapter we learn of the author's aim to "attempt to give a survey of man's cognitive mechanisms", something that "no-one else has hitherto ventured to do". "Cognitive mechanisms" are interpreted liberally to include not only higher conscious faculties but also more rudimentary mechanisms of adaptive behaviour which might represent the evolutionary forerunners of consciousness.

The readership at which the book is aimed is also hard to pin down. It is certainly too cerebral for the mass audiences of *King Solomon's Ring* and *On Aggression*, although there are flashes of the humour and the eloquence that characterise those works. On the other hand, although there is a bibliography to match the undoubted erudition of the author, the text lacks the detailed citations which would encourage the professional scholar to follow up points of special interest.

Librarians should file it half way between Philosophy and Ethology, which is another way of saying that I am only half competent to review it. I lack the knowledge (to say nothing of the confidence) to make statements like "The only philosopher ever to voice similar opinions is the Austrian F. Decker". And I cannot professionally evaluate Lorenz's central philosophical point, which seems to me rather important, that "in the interests of objectivity a scientist must understand the physiological and psychological mechanisms by which experiences are conveyed to men... for the same reasons that a biologist must know his microscope...".

The early chapters include some of the arguments given in *Evolution and Modification of Behaviour* (1966). Certainly these points can bear repetition, having been much misunderstood by Lorenz's critics from the school of Hysterical Environmentalism. Animal behaviour is adapted to its environment. This means there is a sense in which facts about the

world are represented in the animal's nervous system or other parts of its physical structure. Just as a key embodies information about the lock which it is manufactured to fit, so even the simplest protozoan contains knowledge about its environment in the sense that it is equipped in advance to survive in that environment.

Those who have ranted against Lorenz's usage of "innate" have sometimes failed to appreciate that he applies the word not to behaviour itself but to the "adaptive information" of behaviour. This is vividly expressed in his treatment of learning: "Unless one believes in supernatural factors... one has to postulate the existence of innate teaching mechanisms in order to explain why the majority of learning processes serve to enhance the organism's fitness for survival. These mechanisms also meet the Kantian definition of the *a priori*: they were there before all learning, and must be there in order for learning to be possible".

In later chapters of *Behind the Mirror* Lorenz comes on to human culture. As always what he has to say is stimulating, but his comparison of biological and cultural evolution is marred by his unfortunate misconception about how evolution works, and therefore about the nature of adaptation. A junior ethologist is bound to be mindful of Lorenz's own emphasis, reiterated in *Behind the Mirror*, on the biological value of reverence for the ancestral wisdom of tribal elders. This is enough to arouse twinges of remorse over the tone of my own recent criticism of Lorenz's unconscious group selectionism. Perhaps it was unfair to pick on *On Aggression* which, after all, was first published in 1963, just before the reaction to Wynne-Edwards brought us back to our neo-Darwinian senses.

But it seems that nothing has changed. In *Behind the Mirror*, animals are still expected to behave for the good of the species, and

there is still no inkling that the issue is the slightest bit controversial. Lorenz sees a "balance between the factors that make for the invariance of the gene pool and those factors that make for its modification..." which "is adjusted to the degree of variability of the environment". Mutation rate is at its "highest in creatures that inhabit highly variable environments". This last statement fits Lorenz's world view like a glove, but it ruffles all my selfish-genetic hackles and I would have liked to have been told where I could look up the evidence.

The idea of a balance between mechanisms for and against change is developed in the analogy of cultural evolution, where it is thought to include genetically programmed tendencies on the part of the young to revere the wisdom of elders—the White Beard Effect—and at other times to rebel against it. Lorenz gives us some fascinating examples of the predominance of blind biology-like evolution rather than rational planning in the development of human culture, and he correctly identifies natural selection as the common factor. But his is a natural selection between large units—species in the biological case, civilisations in the case of culture—rather than, as it should be, natural selection *within* such large units. If you want a cultural analogue of the fundamental unit of biological natural selection, you should seek the analogue not of the gene pool but of something like the gene.

A reviewer is bound to mention the shortcomings he sees in a book, but in this case they are not new and therefore do not diminish his deep respect for the author's achievements, a respect which is far too solid and real to owe its origin to any White Beard Through the Looking Glass. □

Richard Dawkins is Lecturer in Animal Behaviour in the Department of Zoology, University of Oxford, UK.

Language analogue project

Language Learning by a Chimpanzee: The LANA Project. Edited by D. M. Rumbaugh. Pp. 312. (Academic: New York and London, 1977.) \$17.50; £12.40.

LANA is a laboratory chimpanzee, born in October 1970, who has been learning a specially-designed 'language' and engaging in a number of related experiments at the Yerkes Primate Center of

Emory University, Atlanta, Georgia, since she was just over two years old. The 'language' that she is learning is called, appropriately enough, 'Yerkish'; and her own name is identical with the acronymic abbreviation of the formal title of the project; the LANA project is, in full, the Language Analogue project. With the publication of the present volume, which reports the results of the first three and a half years

work, Lana bids fair to becoming as famous as her conspecifics, Washoe and Sarah, trained by the Gardners and the Premacks, respectively. And deservedly so. The LANA project confirms some of the more interesting, not to say exciting, findings of the earlier research; and it makes its own methodological (and to a lesser extent, theoretical) contribution.

The book falls into five parts, consisting in total of sixteen chapters. There is also a very brief foreword by Karl H. Pribram, in which the point is made that "Washoe, Sarah and Lana—and a whole new generation of scientists and apes—are attempting to spell the end of Cartesian dualism". It is also suggested, rather misleadingly to my mind, that "a great deal can be learned about human language from a careful reading of the early chapters". Ernst von Glasersfeld's "Linguistic Communication: Theory and Definition" (chapter 2) does little to advance our understanding of either the structure or the functions of language. Richard K. Davenport's "Cross-Modal Perception: a Basis for Language?" (chapter 3) is no more than suggestive: it is an extremely important finding for comparative psychology that certain non-human primates are capable of cross-modal perception, but the implications of this finding in relation to theories of the nature and origin of language are not drawn in detail.

The most substantial contribution in part I is chapter 1, by Gordon W. Hewes, on the history and current state of speculation about the origin of language. Hewes (who is the only one of the fourteen contributors not to have worked on the LANA project and been responsible for aspects of its design, its day-to-day operation, or the running of some of the experiments) has probably done more than anyone else to resuscitate interest in glottogenic studies and, more particularly, to revitalise, in the light of recent work in several disciplines, the eminently plausible hypothesis that human language originated in gesture, rather than vocal signals. His chapter, as one would expect, is informed and judicious; although it is rather too sketchy in parts and suffers, in the present context, from being geared, as far as references are concerned, to his recent two-volume bibliography. It will no doubt, however, serve the purpose for which it is intended, that of putting the LANA project and other work in "the Chimpanzee Era of glottogenic research" (pp 38–42) in its historical and currently multidisciplinary context.

Lana's training has been more similar to Sarah's than to Washoe's, being based (although less strictly than Sarah's) on the principles of operant

conditioning. Yerkish, too, is like Sarah's plastic-token 'language' in that its grammatical structure and the form and meaning of its 'words' (combinations of up to nine readily discriminable line-figures superimposed on a coloured background) have been fixed in advance by its designers and are rigidly controlled. The syntax is very simple, although otherwise not strikingly different from that of many natural languages in the use that it makes of word order, sentence particles and various predicative relationships. There is provision for co-ordination and embedding. But so far this facility has not been used in the training programme. Nor have other complexities that it is planned eventually to build into the system. It is probably fair to say that Lana's progress with Yerkish is comparable with the progress that Washoe and Sarah made with their 'languages'. It is still an open question, therefore, and to some considerable extent a matter of definition, whether apes have been shown capable of learning a communication system that is rightly des-

cribed as a language. But the research is undeniably of great importance, and the results that have been obtained so far are challenging.

The principal methodological contribution of the LANA project comes from the total automation and computerisation of the process of recording and analysing all the strings of symbols, both by Lana herself and by her 'interlocutors', at all times of the day. As the contributors point out, this has considerable implications for the development of further hypotheses and the analysis of experimental results. The central chapters of the book provide a full account of both the software and the hardware, of the training programme, and of a variety of experiments carried out so far. Much of this has been reported already at conferences and in the specialist journals; but it is convenient to have it brought together in a single volume.

John Lyons is Professor of Linguistics at the University of Sussex, UK.

Pharmacology of the synapse

Chemical Pharmacology of the Synapse. By D. J. Triggle and C. R. Triggle. Pp. viii+654. (Academic: London and New York, 1976.) £20; \$43.75.

THE five chapters in this book cover the structure and function of the synapse (127 pages); quantitative aspects of ligand-receptor interactions (102 pages); structure-activity relationships: chemical constitution and biological activity (197 pages); the molecular basis of neurotransmitter-receptor interactions (163 pages), and characterisation, quantitation and isolation of neurotransmitter receptors (41 pages). It therefore attempts to cover biological and chemical topics which are of fundamental importance in the understanding of the actions of drugs at receptors.

The first chapter should be helpful as an introduction for chemists and biochemists. The second deals with the relation between dose and response in experiments where this is not complicated by metabolism and transport. Some pharmacologists may feel that the treatment is not as rigorous as it might be, but it is a fair account of current ideas. The third chapter reviews structure-activity relationships at eight separate receptors, and although this is the biggest chapter in the book and

contains much useful information, it is rather fragmentary. Each receptor really requires more extensive discussion and the non-chemical reader may find this chapter heavy going. It also needs some underlying idea to hold the eight sections together and an attempt to supply this is made in the fourth chapter. In our present state of knowledge, however, the molecular basis of neurotransmitter-receptor interactions is very uncertain and the chemist may feel disappointed when faced with an account that is inevitably largely electrophysiological. Understanding the basis is, in fact, going to require further information, which should come from studies with isolated receptors, dealt with briefly in the last chapter. The book, therefore, does not supply all the answers, but it gives a reasonable account of the problems and of the work which has been done to try to solve them.

There are some blemishes. The authors ought to make up their minds whether to use (*d*) or (+) for the sign of rotation and the formula for nicotine is twice given incorrectly (p22, p292); only half the absolute configuration is indicated in the formula of (+)-tubocurarine (p23).

Although most readers will probably find something to object to somewhere in the book, the authors have done a useful public service in collecting together so much information, much of it recent. The subject needs a book of this sort, which will make a useful starting point for students who are new to this kind of work, whether they are

chemists, biochemists, pharmacologists or physiologists. All these will find some part of the book where they will feel at home, and this should encourage them to see their contribution in relation to that of others. Although it may be difficult to write a book all of which will appeal to readers with such different backgrounds, the subject is

not divided up in the way that scientists are. This book is important because it attempts to review synaptic events as a whole.

R. B. Barlow is Lecturer in Chemical Pharmacology at the Medical School, University of Bristol, UK.

Recognising variable patterns

Syntactic Pattern Recognition: Applications. Edited by K. S. Fu. Pp.xi+270. (Springer: Berlin and New York, 1977.) DM 85; \$37.40.

THIS collection of ten papers by different authors is concerned with the application of automatic pattern recognition to electrocardiograms, speech, Chinese ideograms, mathematical expressions, finger prints, remotely sensed imagery and parts of industrial assemblies. The central technical problem is that machines are required to recognise patterns that are not unique. For instance, countless minutely different waveforms should be recognised as clinically normal electrocardiograms. Similarly, two successive finger prints from one right thumb will generally be slightly different, depending for instance on distortion of the skin by pressure while the print is taken. Such differences often make it unexpectedly difficult to make machines recognise what the brain can easily recognise.

There is at least a tenuous analogy between deciding which patterns are *bona fide* finger prints of one right thumb and deciding which strings of symbols constitute a syntactically admissible sentence in a formal language. In both cases a large or infinite set of strings or patterns has to be defined by means of definitory apparatus that contains relatively little information. Furthermore, a finger print consists for instance of a whorl or tented arch which in turn consists of minutiae in various positions; and similarly a sentence consists of phrases which in turn consist of words. This illustrates the general idea that patterns, as well as sentences, can usefully be subject to a hierarchical structural description as in parsing. Because formal language theory is well understood, various workers have tried since about 1964 to do some good with it in automatic pattern recognition.

Chomskian grammars turn out to be

too abstract, too simple, for immediate application to pattern recognition. First, a phrase structure is concerned only with concatenation of symbols, not with the details of their relative positions and shapes. Second, a simple grammar is one-dimensional, whereas finger prints are not. Both of these problems can be overcome to some extent, and the book under review gives usually *ad hoc* details for the different practical applications.

The first chapter is a concise introduction by Fu, whose textbook *Syntactic Methods in Pattern Recognition* (Academic Press, 1974) makes an even better introduction. The standard of the remaining papers is rather higher than in the usual journals, and several contain useful introductions and bibliographies for their application areas. Stallings' paper on Chinese ideograms is particularly good in this respect.

In pattern recognition one can either start with a technique and see how it works in a given application, or one can start with an application and devise suitable techniques. The present book mainly follows the first of these strategies, whereas the papers in *Digital Picture Analysis*, Edited by A. Rosenfeld (Springer, 1976) mainly follow the second strategy and turn out *not* to be straightforwardly syntactic in the pure linguistic sense. The syntactic approach is just one among many; and it has perhaps met its greatest commercial success in reading machines such as the IBM 1287 which are not mentioned in the book under review.

This book is not about established commercial applications but instead reports research explorations of conceivable applications for syntactic techniques, and does not give much idea of the relative efficacy of syntactic compared with other techniques. Nevertheless, it is as good a collection of papers as we are likely to get in 1977 on this topic.

Foundations of population genetics

Foundations of Mathematical Genetics. By A. W. F. Edwards. Pp. viii+119. (Cambridge University: Cambridge, London and New York, 1977.) £5.80.

JUDGING from the title, you might expect this book to be a history of population genetics. It is a fine book; but it is not a history, certainly not in the conventional sense. The book discusses the foundations of population genetics, and to A. W. F. Edwards that mainly means the single locus, infinite population, discrete generation, random mating, constant fitness model. There is some justification for focusing on this model and closely related ones, for, as Edwards points out, "... the elementary mathematical theory [of population genetics] has reached a sufficient maturity to be presented... as a piece of mathematical standing in its own right" (page vii). The approach is purely mathematical, therefore, and the book will be useful to mathematicians and statisticians who wish to have a concise introduction to the essential terminology and concepts of population genetics. It will also be useful to population geneticists, evolutionary biologists, or ecologists who want a thorough review of some of the fundamental models of population genetics.

In elaborating in detail the implications of a few fundamental models, Edwards goes somewhat counter to what has been and remains an historical trend in population genetics, a trend toward generality at the expense of precision. How this trend became established is not completely clear, but Edwards attributes it to the genius of the founders: "One of the inevitable corollaries of the fact that the structure of mathematical genetics was created by three men of exceptional calibre, R. A. Fisher, J. B. S. Haldane and S. Wright, has been that the ground floor of the edifice is scantily furnished. They ascended rapidly to the upper storeys, not always by the same staircase" (page vii).

On the other hand, the quest for generality has characterised not only population genetics but also much of theoretical evolutionary biology. Emphasis has been on the search for principles that apply at all times and to all situations; special cases, or principles with a restricted range of validity, are anathema. What we have learned in the past fifty years is that there are precious few general principles, and these few are so abstract as to be not especially useful.

Edwards has in any event countered the trend towards a superficial analysis of a multitude of models. This seems thoroughly appropriate for a book whose purpose is to present elementary population genetics as a branch of mathematics. Whether the approach is equally valid for those whose interest is in actual, evolving populations is another matter.

In focusing on a few specific models, Edwards has discovered that, as the creators of population genetics ascended to the upper storeys, they left a number of important theoretical gaps below, in the analysis of the simple, fundamental model of population genetics. In a number of instances Edwards has plugged the gaps himself, so the book contains much that is new.

The book focuses on the discrete-generation models of selection in diallelic, triallelic, and multiple allelic autosomal loci as well as sex-linked loci; brief sections are also devoted to models with differential viabilities in

the sexes, selection in heterogeneous environments, and selection with two linked, diallelic autosomal loci. Throughout the book, emphasis is on finding conditions for the existence of polymorphic equilibria and determining when the gene frequency will actually converge to the equilibrium. Considerable attention is also given to the behaviour of the mean fitness function. One attractive feature about the book is a consistent and clever use of triangular coordinates, following a century-old treatise on the subject by Reverend N. M. Ferrers, one of Edwards' predecessors as Fellow and Tutor of Gonville and Caius College.

All in all, *Foundations of Population Genetics* is a thorough, scholarly treatise, and a useful addition to any professional's library.

Daniel L. Hartl

Daniel L. Hartl is Professor of Biology at Purdue University, West Lafayette, Indiana.

Molluscan atlas

Atlas of the Non-Marine Mollusca of the British Isles. Edited by M. P. Kerney. Pp. v+202. (Conchological Society of Great Britain and Ireland: Luton, UK, 1976.) £3.

It is ironical that a major contribution to the study of land and freshwater molluscs in the British Isles should have been published in a year when a catastrophic drought produced a major perturbation on many molluscan populations. The production of this atlas is therefore apposite in providing basis for monitoring ensuing changes. Moreover, it commemorates a century of cooperative endeavour in recording the distribution of molluscs by a succession of dedicated enthusiasts.

This volume deserves recognition by a much wider audience than malacologists, for it summarises in graphical form information collected during the most detailed survey undertaken in this country on any invertebrate group of comparable size. Indeed, it represents a milestone in the development of mapping schemes, and should provide a catalyst to other small organisations undertaking similar projects.

The distribution of 192 taxa is presented on the now conventional 10-km grid maps used by the Biological Records Centre and the information is categorised on the basis of recorded living before or after 1960.

A further refinement is included: the records of the relevant fossils are plotted for those species where there is evidence of changes in the distribution since the last Postglacial period. A promised set of transparent overlays will provide information on a range of environmental parameters and thus enhance the interpretation of the maps, these are eagerly awaited.

Results have already accrued from this survey and these are reflected in the recording of several species new to the British Isles and in the re-assessment of the distribution or taxonomic status of others. Nevertheless, the enduring value of this type of work is the enormous impetus and stimulus it should provide for a wide range of research programmes and other activities.

Many biologists and naturalists will regret the adoption of a number of unfamiliar innovations in nomenclature even though they will applaud the desire to establish uniformity of treatment throughout Europe. This laudable objective would have been more palatable by the addition, to each map, of references to more widely known synonyms. An indication of the habitat range and extra-territorial distribution of each species would have further facilitated an understanding of the recorded patterns. Such limitations, however, should not detract from the value of this atlas.

J. F. Peake

J. F. Peake is Head of the Mollusca Section and Deputy Keeper of Zoology at the British Museum (Natural History).

obituary

L. F. Cooling

DR L. F. COOLING died on Tuesday, 15 February after a short illness. He was 73. His death marks the close of a significant era in the development of engineering science in Britain. Born in Birmingham, he graduated there in physics in 1925 and later gained an MSc for studies of the thermo-magnetic properties of meteorites. In 1927 he joined the Building Research Station at Garston and he remained there until his retirement as an assistant director 41 years later in 1968.

His early work on permeability and evaporation properties of porous building materials formed a good basis for his future research into the engineering properties of the ground. In 1933 he was made head of a soil physics section formed to carry on Prof C. F. Jenkin's work on earth pressure and to study road foundation problems for the Road Research Board. His laboratory in the Stable Block at Garston was the pioneer soil mechanics laboratory in Britain.

Cooling was the only British participant at the first International Soil Mechanics Conference in Harvard in 1936 where he acquired confidence in

his subject. By 1937, when he had been joined by Prof A. W. Skempton, FRS, and Dr H. Q. Golder, he had aroused considerable interest among civil engineers in the practical value of soil mechanics by his investigations of several landslips involving railway cuttings and retaining walls. In particular his diagnosis of the Chingford Reservoir embankment failure, which brought Karl Terzaghi to England for the first time, provided the impetus for the recognition of soil mechanics as an engineering discipline throughout Britain and engineers from many organisations came to the Building Research Station to be trained.

Cooling was practically minded but he never pretended to be an engineer. His lucid understanding of physics enabled him to convince engineers of his reasoning and they had absolute confidence in him. He was unpretentious and always talked sense.

During the war years the emphasis on the investigation and analysis of foundation and earthwork failures grew. The field studies pointed to weakness in the understanding of the in-situ mechanical behaviour of the ground and Cooling initiated a programme of intensive field investigations in which

detailed measurements were made of the performance of structures such as earth dams, tunnels and building foundations.

Cooling's contributions to engineering science were recognised in 1952 by his University with the award of a DSc, this time in engineering, and by the Institution of Civil Engineers who invited him to their membership. In later life Dr Cooling played many leading roles in the committees, societies and journals concerned with the national and international organisation of soil mechanics. He gave the second Rankine Lecture "Field measurements in Soil Mechanics" to the British Geotechnical Society who also recognised his interests in young people by creating the Cooling Prize, to be awarded annually to the best presentation from a young engineer—a function he always looked forward to in his retirement.

Cooling was a keen sportsman. At University he played for the England Amateur football team. He was a Midland Counties Champion runner and an enthusiastic player of shove ha-penny and golf.

He leaves a wife and a daughter.

W. H. Ward

E. Cunningham

Ebenezer Cunningham who died in Corbridge, Northumberland, on February 12 at the age of 95 was a pioneer in introducing the work of Einstein in this country. His father was a cabinet maker; G. D. Cunningham, organist and conductor, was his elder brother. From Owen's School, Islington, he won a mathematical scholarship at St John's College, Cambridge, was Senior Wrangler in 1902 and a Smith's Prize-man in 1904, when he was elected to a Fellowship. After holding lectureships at Liverpool University and University College, London, he returned to St John's in 1911 and until 1976 his home was in Cambridge, where he played an important part both in the Faculty of Mathematics and in his college. His clear and stimulating lectures on branches of applied mathematics are remembered with pleasure and a pupil says of his approach to an unfamiliar

problem, "you were seeing the Senior Wrangler in action."

His first few papers were on pure mathematics but by 1907 he was writing on electromagnetism; in 1909–12 he and H. Bateman, for a time a colleague at Liverpool, contributed papers to the *Proceedings of the London Mathematical Society* on the four-dimensional transformations of the electrodynamical equations. In 1910 he also made a correction to the Stokes formula for the velocity of steady fall of particles in a fluid.

For the next decade his main interest was the study and exposition of Einstein's theories. *The Principle of Relativity* (C.U.P. 1914) gave the first account in English of the Special Theory of Relativity. In 1915 he published *Relativity and the Electron Theory* (Longmans, Green & Co.) and in the second edition (1921) he included an introduction to the General Theory; "Gravitation" was added to the title.

His books emphasise comparison with theory at every stage; in most other accounts it is difficult to see how much of the theory is directly required by experimental evidence and how much, apparently, by pure thought. In 1919, very soon after the announcement on November 6 of the results of the Solar Eclipse Expeditions, he wrote three articles in *Nature* (Vol. 104) on "Einstein's Relativity Theory of Gravitation." In 1921 *Nature* for February 17 was devoted to articles on Relativity and his contribution follows that of Einstein.

He and his wife, whom he married in 1908, were active members of Emmanuel Congregational Church and they made many friends in all walks of life. He bore with courage her loss in 1969 and his increasing blindness. In this he was helped by his strong religious belief and his lifelong love of music.

Harold Jeffreys

G. M. Frank

ACADEMICIAN GLEB MIKHAILOVICH FRANK, the eminent Soviet biophysicist died on October 10, 1976.

Born in 1904, Frank graduated from the University of Simferopol in 1925. From 1929 to 1943, he worked at the Leningrad Physico-Technical Institute and then at the All-Union Institute of Experimental Medicine. From 1943–52 he carried out research in various laboratories of the Academy of Sciences of the USSR. During this time, he became increasingly associated with the Institute of Biophysics of the Academy of Sciences, becoming its Deputy Director in 1952 and Director in 1957. He was elected to the Academy of Sciences of the USSR in 1966.

Frank's research dealt mainly with the effect of ultraviolet light and ionising irradiation on animal organisms, and also the biophysical causes of nervous stimulation and muscular contractions. He made numerous innovations in photobiology, radiobiology and the biophysics of elementary life processes. He demonstrated the difference

in the biological effects of short-wave and long-wave ultraviolet radiation, showing that, in the first case photodenaturation predominates, and in the second photolysis. His work on ultraviolet radiation found numerous applications in Soviet medical practice, including ultraviolet anaesthesia and the treatment of traumas of the peripheral nervous system.

Frank played a leading part in the development of *in vivo* studies of early physico-chemical and functional changes in tissues exposed to ionising radiation. He identified a number of phenomena occurring during irradiation, and developing in the latent post-irradiation period (depression, variations in the oxygen utilisation pattern, changes in the erythrocytes, and in the electrical parameters of the tissues). He also developed the concept of negative feedback in cellular processes.

In 1927, Frank published a paper showing longitudinal sections of muscle fixed at rest and during isometric contraction at various initial lengths. He obtained the striking result that in con-

tracting muscle, the width of the A bands was independent of muscle length. This was a foreshadowing of the results which in 1953–54 contributed to the establishment of the sliding-filament theory of muscle contraction. His continued interest in this area was seen when he attended the Discussion Meeting on Muscular Contraction at the Royal Society in November 1963.

His major works include *Approaches to the in vivo investigation of the physico-chemical processes of nervous activity* (1954), *Early reactions of the organism to irradiation in dependence on local perturbations* (1955), and *Physico-chemical and structural principles of biological processes* (1960). He was co-editor of the radio-biology section of the second edition of the Soviet *Large Medical Encyclopaedia*.

For his services to Soviet Science and Medicine, Frank was twice awarded the Order of Lenin (the highest civil award) and four times the Order of the Red Banner of Labour. His research twice received a Stalin (now State) Prize. *Vera Rich*

Sheina Marshall

DR SHEINA M. MARSHALL, OBE, FRS, died at Millport on 7 April 1977.

After holding a Carnegie Scholarship at Glasgow University, during which she showed her research abilities in a study of the behaviour and structure of *Hydra*, she joined the staff of the Scottish Marine Biological Association's laboratory at Millport in 1922. Here she started immediately in the field of research in which she was to be engaged for the rest of her life with the most detailed study yet made on the feeding of the copepod *Calanus* and a description of a new species of dinoflagellate.

She then began a remarkable collaboration with A. P. Orr, chemist on the Millport staff, through which they became known internationally as pioneers in the study of marine production. Starting with experiments on the photosynthesis of diatom cultures in bottles submerged in the sea, they proceeded to their classic investigation of the seasonal changes in nutrients and phytoplankton in Loch Striven. In this work there can be seen the seeds from which much of the modern research on productivity has developed.

They then turned their attention to the biology of *Calanus* and other smaller copepods which form a major constituent of the zooplankton responsible for secondary production. In part

of the work on *Calanus* they were joined by A. G. Nicholls. A full study was made at sea of the general biology of these copepods, including their vertical distribution, successive generations throughout the year, their methods of feeding and chemical composition. This was later supplemented by experimental observation in the laboratory on respiration, food requirements, and excretion both in the adult and all young stages. By the use of radioactive phosphorus they showed its very rapid transfer to the ovaries and developing eggs and embryos, thus confirming their theory that abundant food is necessary for egg laying resulting in an adaptation whereby the hatching of the nauplii coincides with diatom outbursts.

After the death of Orr in 1962 Sheina Marshall started further collaboration with E. D. S. Corner, biochemist at the Plymouth laboratory of the Marine Biological Association. Thus her remarkable expertise and knowledge of copepod biology has been made available to a new generation of workers in the field of marine production. Her last investigation was concerned with the overwintering generation of *Calanus* in which it was shown that a partially carnivorous diet is probably necessary for survival.

In 1928 Marshall and Orr went with the Great Barrier Reef Expedition to Australia. There they undertook a similar seasonal investigation to that

made in Loch Striven on the nutrient and phytoplankton cycles in the reef area. This was the first to be done on this scale in tropical waters. Sheina, always indefatigable, made observations also on the occurrence of symbiotic algae in coral planulae, and with Orr investigated the ability of certain corals to rid themselves of silt.

On their return to Millport they made a short investigation, with A. G. Nicholls, on the growth of the early stages of the herring in the Clyde Sea Area, which is probably the most complete observation made on a single brood.

During the war she was engaged on two projects in the applied field, namely the fertilisation of sea lochs and the production of agar from the seaweed *Gigartina*.

Although not a systematist she had a special interest in tintinnids on which she wrote a Barrier Reef report and prepared plankton identification sheets for the International Council for the Exploration of the Sea.

Her work with Orr was brought together in their book *The Biology of a Copepod*, and she amplified and prepared for press Orr's Buckland lectures given in 1957 to form the book *The Fertile Sea*.

Much travelled, her loss will be felt by many friends all over the world who got to know her sterling qualities.

F. S. Russell

what's new – microscopes

In addition to the regular Newly on the Market section in *Nature*, special features on a particular type of laboratory equipment or instrumentation will be published in this and forthcoming issues. The issue of 18 August will be on Chromatographs and ancillary equipment and that of 20 October on Spectrometers and ancillary equipment.

The purpose of a special feature will not be to give listings of every item in the range of the manufacturers mentioned but to take a variety of equipment of interest in that feature area and give an idea of what kinds of instruments are available and from whom.

This feature on Microscopes and ancillary equipment covers optical and electron microscopes, stereomicroscopes, wide-field and measuring microscopes, teaching microscopes, stages, ultratomes and cryomicrotomes, fluorescence and metallurgical microscopes and other related items.

Available from Philips is a high-performance scanning electron microscope PSEM 500 interfaced with a fully-focusing wavelength dispersive X-ray spectrometer, the PSEM 500X, not only permits analysis of X-rays from $Z=5$ to $Z=92$ but is the first such system to use the vertical spectrometer orientation—a configuration which offers the highest mechanical reproducibility—without the need for an optical microscope. Instead, a new standard in specimen height accuracy and reproducibility is achieved via the unique, fully-eucentric goniometer coupled with its 4.6 mm fine Z-adjustment (in 0.2 μm steps) and the large (210 mm) Rowland circle of the spectrometer. An extremely high-vacuum system (10^{-6} torr, inclusive of the spectrometer assembly) vastly improves practical light-element detection. Thus, absorption of 'soft' X-rays from light elements, due to specimen contamination, is seldom encountered. The same vacuum system, without modification, allows operation with optional higher-brightness sources—a particularly valuable facility for excitation of X-rays from light elements. The standard 50 kV electron optics of the PSEM 500 is ideal, when using an energy dispersive X-ray detection system, for unambiguous excitation of K-line X-rays from heavier elements.

The larger excited volume of X-rays, when using 50 kV electrons, can also facilitate easier trace-element detection. The energy dispersive and wavelength dispersive spectrometers can be in operation at the same time, thus giving an optimum choice of the characteristics of each type of spectrometer.

LKB Instruments Ltd present an advanced ultramicrotome and a new 'whole animal' microtome/cryomicrotome. The Ultratome IV is the latest, most advanced ultramicrotome developed and manufactured by LKB-Produkter in Sweden. It will prepare large-area thick epoxy sections for scanning transmission or high voltage electron microscopy; and serial ultrathin sections for transmission electron microscopy. A system of push buttons allows knife alignment and approach to the specimen to be conducted entirely from the control panel. The gravity-powered cutting stroke ensures constant and reproducible cutting speeds regardless of section size or

LKB Ultratome IV

thickness, and this, in conjunction with the magnetic coarse feed, will prepare large, even sections for optical microscopy. Likewise, when used with fine thermal feed, the Ultratome will produce grid-sized sections to any thinness required between 0 and 200 nm. Other advances include specimen trimming and a new viewing system for selected area trimming; the orientation head offers precision of adjustment and provides wide specimen orientation possibilities. Ten glass knives can be evaluated at one time for edge quality and angle. There are new collection facilities for both thick and ultra-thin

sections. The PMV Cryomicrotome (made for LKB by Palmstiernas Mekanismiska Verkstad, Stockholm) is a heavy-duty microtome in a cryocabinet. Specimen size need no longer be a limitation with the PMV since material of up to 45 cm $\times$ 15 cm can be sectioned. Therefore experiments can be carried out using larger animals, a feature which could provide obvious advantages in the testing of new pharmaceutical products for eventual human use. Simple operation giving reliable and reproducible results identifies the PMV approach.

Vickers Instruments, a division of Vickers Limited, manufacture a comprehensive range of optical microscopes supplemented by selected instruments from a sister Company, Nachet of Franche, and from Union Optical of Tokyo. The Company also acts as sole UK agent for Metallographic and Mineralogical specimen preparation equipment by Struers of Copenhagen. Many recent innovations include an inexpensive closed-circuit television attachment suitable for routine industrial applications as well as the more traditional teaching role; a direct-reading micro-measurement system based on the image-shearing principle and capable of sub-micrometre accuracy even in inexperienced hands; the Nachet NS400 Research microscope featuring an optical system which allows all techniques to be undertaken using a single set of objectives, and the Union Versamet, an inverted Metallographic instrument allowing instant selection of bright field, polarisation, dark ground or Nomarski interference contrast. The most significant development has, however, been the introduction of a completely new series of instruments, collectively titled M17, for research and routine applications in both Materials and Life Sciences. The M17 series is designed to accept many interchangeable accessories but the availability of several basic microscope stands allows the user to select precisely those facilities which are required. The basic range already includes purpose-built models for incident light, transmitted light and dual illumination (one offering an extra-wide 25 mm field of view) while a totally

new incident fluorescence illuminator combines simplicity of operation with true research capability. A routine fluorescence microscope is also available and instruments for analytical work in polarised light are to be released soon. The flat-field objectives, both achromats and apochromats, are completely new designs, giving improved colour corrections over the widest 25 mm field of view. A comprehensive range of fully interchangeable camera equipment, including electronic exposure units, may be fitted to any model from the M17 series; particular features of the system being the retention of full binocular vision during exposure, the absence of the usual auxiliary focusing adjustment and the facility to rotate both framing graticule and camera body to capture oblique features of the specimen.

Gillett & Silbert produce a broad range of microscopes from the student to the research level with the emphasis on those used routinely in the laboratory; the range includes photographic systems and a £100,000 consignment was recently delivered to Korea.

Circle No. 48 on Reader Enquiry Card

Kratos Ltd, AEI Scientific Instruments (formerly AEI Scientific Instruments) are long-time manufacturers of electron microscopes, two of which are featured here. The Corinth 500 is a high resolution electron microscope with 5 Å resolution imaging, multiple specimen facilities and multiple accelerating voltages of 20, 40, 60 and 80 kV. A double condenser lens system reduces specimen damage; there are excellent viewing facilities— $\times 240,000$ top magnification and excellent recording facilities—70 mm roll film camera is standard equipment. The Corinth has very high stability supplies— 5×10^{-6} per min and a foolproof fully automatic vacuum system. Also X-ray leakage rate is very low—less than 0.1 mR h^{-1} . Additional optional extras include viewing hood for daylight working, scanning attachment for reflection scanning, electron imaging of larger specimens,

AEI Corinth 500

solid state detector attachment for simultaneous transmission imaging and X-ray analysis of selected areas. Because of the high penetration of the electron beam, much thicker specimens can be investigated in a high-voltage electron microscope than in a 'conventional' instrument operating with an accelerating voltage of 100 kV. For this reason in particular, metallurgists and material scientists in the 1960s were the first to take advantage of the high-voltage technique. The thicker specimens which could be used were more representative of the bulk material from which they were prepared and they consequently revealed information about the material which could not be obtained by any other means. The high-voltage microscope also provides the biologist with facilities to exploit the exciting technique of stereoscopic micrographs. The thick sections of biological material make ideal subjects for viewing and photographing from two different angles, and, for the first time, it has been possible to record effective three-dimensional images which provide quite remarkable information and a new

AEI EM7 Mk II

understanding of structure. One of the most recent applications of the high-voltage microscope is in geological research. Using specimens prepared by the ion beam technique, only a small part of the thinned section can be investigated with conventional electron microscopes. But, with a million-volt instrument, information can be obtained from a far greater area of the section which is more representative of the bulk material and the advantages of the technique hold promise for many new far-reaching discoveries in this field. The EM7 Mk II high-voltage electron microscope has a 5 Å resolution, a wide operating voltage range—100–1250 kV, can be used for critical voltage experiments and radiation damage experiments. It has wide magnification range— $\times 63$ to $\times 1,250,000$ and is suitable for grid searching and high resolution applications. Rotation free imaging— $\times 4000$ to $\times 1,000,000$ enables an area to be viewed with zoom magnification without the image rotating. Operation is very easy, all controls are conveniently placed, specimen chamber is within easy reach of operator. There are excellent viewing and recording facilities and accessories available are solid-state elemental analyser, closed-circuit TV system, image intensifier, radiation monitors, plate desiccator, liquid helium anticontaminator, high resolution diffraction stage, vacuum coating unit.

Wild Heerbrugg Ltd, Switzerland, present a photomicroscope, the Wild M400. This system opens up even to the non-specialist the hitherto rather difficult photographic magnification range from 1:1 to 60:1. Binocular

Wild M400

observation, zoom optics 1:5 and completely automatic exposure and film transport allow the observer to concentrate entirely on the specimen and format limits. Owing to its modular construction with different stands and other accessories for incident light,

Wild M5A

transmitted light, bright field and dark field, polarisation etc, the Wild M400 can meet all the demands of present-day macroscopy. The new Wild M5A Stereomicroscope has several new design features, particularly the availability of a unique new coaxial incident illuminator which directs the light of a 20 W halogen illuminator along the two optical trains, with the result that the image is free from the glare which is often so troublesome in the examination of highly-reflecting metallurgical specimens or of multilayer thin-film materials such as integrated electronics circuits. Additional objectives and interchangeable eyepieces extend the magnification range to $\times 250$. A metal hood, which unites with the baseplate, protects the instrument from dirt and from transport damage. The modular design enables a variety of observation techniques and supplementary sets of accessories (for example for photomicrography and television microscopy) to be applied.

Circle No. 50 on Reader Enquiry Card

Available from **Stanton Redcroft** is a hot stage microscope unit, the HSM-5, a unit which enables the user to observe materials under controlled conditions over the temperature range ambient to 1000°C . The unit may be used with any large working distance microscope especially with a stereoscopic microscope. 35 mm photomicrography and time lapse and high speed cine photography are readily possible. The sample temperature and the intensity of the light reflected from the sample can be accurately followed. The sample is held in a standard DTA sample pan. Specification: water-cooled micro-furnace with temperature range ambient to 1000°C . Rapid temperature response and cooling from

1000°C to below 100°C in less than 5 min; wide range of switch selected linear heating (and cooling) rates from 1 to 100°C per min. Rapid establishment of isotherms to within $\pm 1^\circ\text{C}$. Full atmosphere control, small swept volume for ready coupling to a gas analysis system. Accurate sample temperature measurement using plate type Pt v Pt-13% Rh thermocouple. No special sample preparation necessary. Quartz window for viewing. Can be rotated to remove condensed volatiles from the field of view. The unit has been used to study a range of reactions including the fusion and decomposition of organic and inorganic materials, oxidation of metal powders, the behaviour on ignition of pyrotechnic mixtures.

Bausch & Lomb UK Ltd market a wide variety of microscopes, stereomicroscopes and stereozoom microscopes for use in education, industry, electronics, R&D, medicine and the Laboratory. The ESM 25/100 Microscope is ideal for elementary science teaching, as well as a highly practical instrument for field observations. It combines two magnifications in one instrument, the $\times 25$ position for low power scanning and for macro specimens up to 10 mm thick, the $\times 100$ position for higher power detailed study. Model SSM Student Stereomicroscopes ($\times 15$) and Model ST2 Science Teaching Zoomscopes ($\times 50$ to $\times 200$) are both low-priced durable student microscopes. The Academic Stereozoom series of microscopes are also designed for science teaching, with zoom optics, 'student proof' construction, king-size stage and 'dial a light' facility—a three-way illumination system giving a choice of reflected light, transmitted light or a combination. The Stereozoom Series (5 and 7) with exclusive Power Pod gives real

Bausch & Lomb Stereozoom

3-dimensional images by means of the Greenough design which features two complete converging optical systems that have a uniform optical path from eyepiece to objective. Both systems are aligned to focus at a single point assuring true 3-dimensional imagery, as each system fully utilises its own lenses. Zoom optics are standard and the sealed Power Pod prevents dust from entering the optical system, also stops image jump and image blackout. A flat-field optical system is integral and flexibility of attachment options covers a variety of Power Pods, eyepiece magnifications, supplementary lenses, stands, illuminators, polarising and photographic accessories.

The Tiyoda Super Widefield MT-B Microscope, available from **Hall Bros (Optical) Ltd** is a new concept in microscopy. This microscope is unique in design and construction, the designers having consulted professionals from all branches of medicine and science. Super Widefield eyepieces allow fatigue-free viewing of a field 90% larger than that seen with conventional widefield

Hall Bros Tiyoda MT-B

eyepieces and a new patented 11 element Apochromatic condenser complements the Plan Apochromatic objectives $\times 2$, $\times 4$, $\times 10$, $\times 20$, $\times 40$ and $\times 60$. With these there is a $\times 1$ Plan Achromat which is perfectly parfocal with the other objectives. All controls are grouped together in one zone, letting the operator control the focus, aperture, stage movement and condenser adjustments with ease. For the first time super widefield photography is possible. A $\times 0.66$ lens is built into the phototube, and a low power photo-eyepiece combines to cover a rectangular format extending right to the edge of the visual field, e.g. with the Plan Achromat $\times 1$ objective an area of 14×22 mm can be recorded on 35 mm film.

Circle No. 53 on Reader Enquiry Card

Nikon manufacture a wide range of microscopes and ancillary equipment; research microscopes of various types—the Apophot, the Multiphot and the Biophot, conventional optical microscopes (the L-Ke, S-Ke and S-KT ranges), polarising (Model POH-3) and fluorescence (Model FL/FT) microscopes, stereoscopic (Model SM), metallurgical (Models ME, MSE, S-Epi, hole and surface-finish microscopes), inverted (Models M, MS and MTD), photo-ciné micrographic equipment and a wide range of interchangeable accessories. The Apophot has a sturdy console construction, a trinocular eyepiece tube, built-in magnification

Nikon Inverted Microscope

changer, interchangeable nosepiece system, a variety of stages, interchangeable condenser system, zoom Koehler illumination and various light sources available, Phase contrast (PC), interference-phase (IP), differential interference (DI) and polarising (P) attachments, also photomicrographic (PM) and ciné facilities and optional projection screen ($\times 6$ to $\times 3,000$). The Multiphot is capable of large-format photomacro- and photomicro-photography. The Biophot can be used for photomicrography, has a trinocular nosepiece tube, interchangeable arms, six-objective revolving nosepiece, filter facility, large stage and swing-out condenser, Koehler illumination, interchangeable eyepiece tubes and stages, P, IP, DI and PM facilities. The M, MS and MTD range of inverted microscopes, are particularly useful for tissue culture research. Interchangeable eyepiece tubes, PC, IP, DI and P facilities, also cine PM attachments, projection

screens and a specimen incubator. (Model M magn. $\times 6$ to $\times 2,000$). Model MS has a diascope illuminator and can be supplied in a biological or metallurgical form ($\times 30$ to $\times 2,250$; for PM, $\times 20$ to $\times 1,500$). Model MTD is specifically for tissue culture research ($\times 100$ to $\times 200$). Models ME, MSE, S-Epi (metallurgical) have magnifications in the range $\times 25$ to $\times 2,700$. The SM range of stereoscopic microscopes include the SM-5 ($\times 10$ to $\times 60$), the SMZ-2 stereoscopic zoom microscope ($\times 4$ to $\times 120$), the SMZ-6 ($\times 45$ to $\times 120$), various bases, pillars, stages, stands and PM facilities. The POH-3 polarising microscope has an extra long range of stage elevation, interchangeable single and multiple nosepieces, built-in transformer and Koehler illuminator, interchangeable eyepiece tubes, graduated, circular rotatable stage and epi-illuminator. Models FL/FT fluorescence microscopes have all types of filters, PC and PM facilities. **Circle No. 54 on Reader Enquiry Card**

Graticules Ltd have a comprehensive range of eyepiece and stage micrometers, counting and sizing graticules and the England Finder. Recently developed products include measuring instruments incorporating graticules, pocket measuring magnifiers and portable measuring microscopes. The Co-ordinate Measuring Microscope is a travelling microscope allowing measurements to be made over an area of $250\text{ mm} \times 250\text{ mm}$. Accessories include a rotary work table, light box, electronic digital readout, projector or 45° viewing heads and a choice of objectives, eyepieces and graticules.

The Portable Measuring Microscopes (Series 800) are versatile hand held microscopes calibrated to read down to

Graticules Series 800

$5\text{ }\mu\text{m}$. Accessories include miniature light fittings, spray droplet analysing graticules and plated through hole optics sets. The series 800 are designed for use on the work bench, in the laboratory, drawing office and so on, ideal anywhere where a full size microscope would be inconvenient to use and difficult to set up.

Circle No. 55 on Reader Enquiry Card

Pyser Ltd. for both teaching and research applications, the Swift M1000E series microscopes have a newly-designed base and a low-cost phase contrast unit. The base incorporates pre-centred 6 V 20 W built-in halogen illumination, the brightness of which can be adjusted by means of variable light control. The semi-Koehler illumination system is fitted with a centerable field iris; an alternative mains base with a built-in 240 V 30 W lamp can be supplied. Monocular, binocular,

Pyser Swift M1000 E

trinocular and tutor-tube versions are available; also a wide choice of stages to meet varying budget requirements. The plain stage is drilled to take stage clips or an attachable mechanical stage with controls on the top; a built-on mechanical stage has coaxial controls at the side while another built-on mechanical type has low-position vertical drive coaxial knobs. Coarse and fine focusing operates on the stage, which moves on precision ball bearings. The coarse adjustment is fitted with a patented clutch. These instruments can be used for dark and bright ground microscopy as well as phase contrast. In addition to the normal ranges of achromats and plan achromats, new objectives of $\times 40$ and $\times 100$ have been introduced for both bright field and phase contrast in the semi-plan form. **Circle No. 56 on Reader Enquiry Card**

nature

30 June 1977

Carry on talking

YOU MIGHT think that, what with the Select Committee on Science and Technology, the Parliamentary and Scientific Committee, The Royal Society, the Council of Engineering Institutions, the British Association for the Advancement of Science, the Council for Science and Society, Chief Scientists in governmental departments and an Advisory Board for the Research Councils, there is no shortage of channels in Britain by which scientists could make their views known to politicians and by which politicians could learn more about science and technology. You would be wrong. Scientists and politicians generally only talk to each other when things are going wrong, and even then it is usually directors of laboratories or scientific administrators who speak for science. A modest welcome, then, for the initiative of the Anglo-German Foundation for the Study of Industrial Society in trying a new format.

The foundation, in collaboration with Mr Ian Lloyd, MP, chairman of the Select Committee's sub-committee on science, recently invited a small number of MPs and staff members of the committee to spend a day and a half listening to six scientists and engineers describing their fields of interest, the prospects they see and the difficulties they face, not simply in the intellectual sphere but also in securing adequate support. The topics covered were construction,

power generation, immunology, genetics, microelectronics and the earth sciences.

In many ways the initiative was imaginative: the group was small enough for round-the-table conversation to flow easily, the scientists and engineers had ample time to describe their work, no one was angling for funds or speaking for the public record. On the other hand the MPs, for whom the show was staged, were conspicuous mostly by their absence; by half way through the gathering, Mr Lloyd was the only one left. There were, no doubt, other pressing matters to be attended to, and the harsh realities of the ballot box make little allowance for how well an MP has briefed him or herself, least of all in science or technology. So the welcome for the initiative must be tempered by some concern about whether politicians really value such exchanges. And if they do, the foundation has to decide on what lines another meeting should run. Should MPs be treated to completely new faces each time or should the effort be made, whatever the accusations of cosiness, to keep a nucleus of scientists and engineers together in the hope that good relations will develop? There is much to be said for the latter policy, tempered, of course, by new faces where necessary. For the initiative should develop into a talking shop, not a lecture series. □

Whose venture, whose gain?

THERE were signs at a recent meeting in Basel that the rising risk-consciousness reflected, for instance, in the endless debate on recombinant DNA and in the witch-hunt for environmental carcinogens, is increasingly losing the sympathy of research scientists. The meeting was not about potential environmental hazards from research; the scientists were all there at the invitation of Hoffman-La Roche to celebrate their research director's 60th birthday with a series of talks on the contribution of fundamental research to the medicines of tomorrow. Participants however seemed almost equally preoccupied with the possibility that the fruits of that research might never reach the market.

The main source of unease, of course, is the fear that far-reaching defensive action may be taken on the basis of questionable evidence. This has already happened with saccharin in the USA; whether in the end the saccharin link with bladder cancer is or is not substantiated, the fact remains that the evidence on which it has been condemned is widely regarded as inadequate. Professor Peter Cerutti implied that the over-enthusiastic use of the Ames test for carcinogens could very well lead to similar over-reactions. The Ames test depends on the correlations between mutagenic effects of chemicals on bacteria and their carcinogenic effects in whole animals. But the bacteria used in the tests are much more sensitive than animal cells, whose repair mechanisms for chromosomal damage give them complete protection from chemicals at doses that would produce a positive result in Ames bacteria.

As Professor Burgen unarguably remarked in his summing-up, "We must be cautious but not timid". After

all, nothing venture, nothing gain. But one does have to be sure that it is not the public health that is being ventured for the gain of pharmaceutical companies. And from that point of view, it is not at all clear that the public is its own best friend. A recent survey by Sir Richard Doll and his colleagues, for example, illustrates once again how enormously doctors over-prescribe anti-microbial psychotropic drugs (*British Medical Journal*, 1, 1561; 1977).

The hazards of over-use of antibiotics are well known, and the natural ability of virulent strains to acquire resistance to drugs has often been emphasised in the course of the recombinant DNA debate. The hazards of psychotropics, of which the most popular are Roche's own Librium and Valium, are not as well known. But as the authors of the *BMJ* article point out, with about 10% of males and 20% of females now taking psychotropic drugs, it is necessary to ask questions about, for instance, their possible effects on driving and other skills that require judgment.

This is not a case of the pharmaceutical industry foisting on the public drugs which carry unacceptable risks; antibiotics are life-savers, and psychotropics are certainly invaluable in some circumstances. It is the unnecessary use of the drugs that creates the unacceptable risk. However, people are not rational about the acceptability of risks. Recent publicity shows that they will insist on being allowed (or even encouraged) to smoke, or to drive without seat belts, both of which carry large known hazards, and to accept the risk of disease to an unvaccinated child rather than minuscule risk of damage by vaccination. □

Nutrition planning: the poverty of holism

Donald S. McLaren, of the Department of Physiology at Edinburgh University's Medical School, criticises the approach of the planners to the problems of world nutrition

SINCE the World Food Conference in Rome in 1974 there has been a rising tide of proposals for nutrition planning, policies and strategies on both national and international scales. The United Nations, for example, has given its blessing through the FAO/WHO report on 'Food and Nutrition Strategies in National Development', and has further encouraged the trend through the choice of 'The importance of national and international food and nutrition policies for health development' as the topic for technical discussion at the recent World Health Assembly. But the proposals are shibboleths of holism that, lamentably, have gone unchallenged.

The holistic approach has undoubtedly had its triumphs, where the problem was appropriate and the means available made it amenable. The Manhattan Project and the American and Russian space programmes are obvious examples. But the disappointing results in medicine of the American Heart, Stroke and Cancer programme and of Britain's National Health Service, and the failure of numerous attempts to control population increase, suggest that in certain areas of social action guerilla tactics and not a war machine are required, giving flexibility, accountability and proven effectiveness. Nutrition is just such an area.

The new breed of nutrition planners have a disturbing predilection for coining vague neotechnologisms and drawing maze-like flow (or are they ebb?) diagrams. That is bad enough. But they also choose to ignore those harsh realities that do not fit into their preconceived schemes. Ironically, a prime example is the phenomenon as ugly as its own 'neotechnological' name: Agripower. The probing of the United Nations Research Institute for Social Development and others, for example, recently highlighted by Susan George in *How the Other Half Dies: the Real Reasons for World Hunger*, show how the world's poor and hungry are increasingly at the mercy of vast agri-business corporations (chiefly from the United States), of Western governments with their food 'aid' policies, and of supposedly neutral multilateral development organisations, like the World Bank—all of them, so the argument runs, working in collusion with local elites nurtured and protected by the powerful in the developed world.

Then there is the case of *Scientific American* devoting an entire issue to food and agriculture. The problems of food and nutrition were there dismissed as being entirely technological in nature and capable of solution by "additional technology and capital from the developed countries"—a root cause rather than a solution. Ironically, the numerous lavish advertisements documented the frightening story of US agripower that was shunned in the text. Rarely do the institutions responsible permit themselves to make statements on the ethical implications of their activities. It probably takes someone like the former US Secretary of Agriculture, Earl Butz, to admit that "Food is a weapon. It is now one of the principle tools in our negotiating kit"—and we know what happened to him.

What has been ignored throughout such deliberations is the different nature of the two problems of food supply and human nutrition. It was this misconception which contributed to the failure of the UN Freedom from Hunger Campaign in the mid-1960s and to the Great Protein Fiasco of the early 1970s, as I pointed out in *The Lancet* at these times. Food shortage is a necessary but not adequate cause of undernutrition. There is many a slip betwixt the cup of

food supply and the lip of hungry man. Problems with the former are necessary, but not adequate, causes of those of the latter. That is why the Green Revolution has not resulted in less malnutrition.

Nutrition planners state that past efforts failed, if failed they did, because they were piecemeal and for no other reason; they claim that a new planned approach must succeed because it is holistic and not piecemeal. Now the term 'whole' has two senses, as Popper indicated in *The Poverty of Historicism*: the totality of all the properties or aspects of a thing; and the special properties of certain things which make them appear to be an organised structure rather than a 'mere heap'. Popper's argument is clear: though wholes in the latter sense have often been made the object of scientific study (notably by the 'Gestalt' school of psychology), in a social context the 'organised structure' in no way applies and holism is inappropriate. Methodological problems have not been surmounted and there is no reliable procedure for building hypotheses based on well devised observations, experiments or rational deductions. Holistic or Utopian social engineering is always public and not private, aims at remodelling the whole of society and extending the power of the state, and smacks of tyranny. The alternative is piecemeal social engineering, the word piecemeal having no pejorative sense but meaning just what it says—piece by piece or part at a time.

Past achievements of the piecemeal approach to nutritional problems, it is true, are not impressive. Iodisation of table salt is effective against simple goitre. Fortification of staple foodstuffs has helped to maintain optimum micronutrient status in many populations. Prevention of the most common deficiency, iron, remains unachieved everywhere. Classical vitamin deficiencies have been influenced most by political action and social change—the disappearance of beriberi and xerophthalmia from Japan in the early part of this century, of pellagra from the southern United States initiated by the immigration laws in the 1920s, and the emergence of rickets in British Asian immigrants. The widespread intractable problem of the malnutrition-infection complex of early childhood in developing countries has deep socio-economic roots. Mothercraft and nutritional rehabilitation centres have made modest but real contributions.

In those communities where overnutrition and nutrition-related degenerative diseases are rife, it remains to be seen whether the health of the increasingly diet-conscious public will benefit from the multifarious and often conflicting advice it is being offered. In the meantime the fact is that nutrition remains largely one of Medawar's 'kitchen arts'—a science insufficiently underpinned by theory. A halt should be called to the present mania for holistic day dreaming. Research efforts should be renewed to bring order to the present 'mere heap' so that sounder measures may result, piecemeal though they may be. The WHO's resolution at its recent assembly, urging the eradication of the severe clinical forms of malnutrition by the turn of the century, offers at least some hope. □

Hospital meals: effective against malnutrition?

To get more than enough

Colin Norman reports on a massive research effort to combat hunger and malnutrition proposed in Washington last week

A RECORD harvest in the key grain producing countries last year and the prospect of another bumper wheat crop in the United States this year have temporarily removed famine and hunger from the daily headlines. But, with international grain reserves still at a dangerously low level, a catastrophic food shortage in many parts of the world is still only one poor harvest away. Moreover, even if luck continues to hold, there's little room for complacency: according to widely accepted estimates, between 500 and 1,000 million people are already chronically underfed, and rapidly increasing population in most developing countries is continuing to drive up food demand.

Against that grim background, it may seem like the height of folly to suggest that "it should be possible to overcome the worst aspects of widespread hunger and malnutrition within one generation". But that is the conclusion of a major study published last week by the National Academy of Sciences*. One of the most intensive investigations of world food prospects yet put together, the study took two years and involved some 1,500 people; the effort was coordinated by a committee headed by Harrison Brown, professor of geochemistry at Caltech.

The committee's optimism is founded on the expectation that a massive research effort on a broad spectrum of agricultural, social and population problems could lead to a doubling of agricultural production in the developing countries and more equitable distribution of food during the next quarter century. Such an expansion would, in theory, be sufficient to cope with increased food demand from rising population and affluence, and it would also provide an increase in food consumption per capita worldwide.

But the committee is also quick to acknowledge that science and technology will not alleviate widespread hunger by themselves. Basic social changes will be needed to ensure more effective distribution of available food and to reduce poverty, though the committee's report does not advocate any specific social remedies. More attention to nutrition policies will also be required in both the poor and affluent countries, and there must also be renewed efforts to hold down the explosive rate of population

growth, the committee states.

Given the complexity of the world food problem, the committee's optimism is surprising. During the past few years there has been a fundamental shift in the food picture as grain reserves have dwindled to less than a third of their 1970 level and more countries have become dependent on the North American breadbasket to meet their food demands. After a decade of stability, crop prices have fluctuated wildly, aggravating problems of hunger and malnutrition in the poorer countries. And the increasing reliance on North American agriculture to meet world demands raises the grim possibility that a failure of the United States and Canadian harvest would have dire consequences.

Numerous and complex

The roots of the problem are numerous and complex, but one of the chief factors has been rising population in many developing countries which has caused food demand to outstrip production. According to figures in the Academy's report, although food production in the developing countries rose at an unprecedented rate of 2.8% per year between 1960 and 1975, demand for food increased by 3.5% per year. Consequently, a growing number of countries have joined the long list of food importers and there has been virtually no increase in per capita food consumption in the developing countries.

And the prospects for population growth don't give much room for optimism. Although there are recent signs that world population growth is beginning to abate, there are likely to be at least 6,000 million mouths to feed by the year 2000, and some 90% of the growth will take place in the developing countries. World population has recently passed the 4,000 million mark. To feed that many people and provide even a modest increase in per capita consumption will require Herculean efforts. According to the Academy study, the developing countries will need to increase their food production by about 3-4% per year, while stepping up efforts to reduce their birth rates and providing a more equitable distribution of food.

The task will require a major infusion of funds into research, particularly in the United States, and structural reforms in research programmes and in the political and agricultural systems of many countries.

High yield rice under test

Though the committee accepts that the task will not be easy, it states that "a latent political will now exists in numerous countries which could be mobilised in a mutually supporting fashion to commence and support such efforts".

In the past, increases in agricultural production have largely been won in two ways: increasing the acreage under cultivation and improving yields per acre. There have recently been sombre warnings, however, that marginal lands are being taken out of production in some parts of the world because of such problems as desertification and soil erosion and flooding caused by deforestation. The prospects for increasing agricultural acreage are therefore poor, and the Academy study predicts that annual increases in crop area will be unlikely to exceed 1% per year over the next 25 years. The bulk of the increase in agricultural production will have to come from boosting yields per acre.

The committee offers a shopping list of research programmes which it says should be stepped up to help increase yields. They include the development of fertilisers for use on tropical soils, efforts to improve irrigation and soil conservation, methods of reducing crop losses between the farm gate and the market, the development of more efficient farm systems and the application of biological methods of pest control. Two programmes are expected to be crucial to the long-term prospects for increasing yields, however. They involve boosting the efficiency with which crop plants use solar energy through photosynthesis, and efforts to develop cereal plants capable of utilising nitrogen directly from the atmosphere instead of having it supplied as chemical fertiliser.

At present, some 45 million tons of fertiliser is used per year worldwide. To bring about a doubling in food output during the next quarter century

*World Food and Nutrition Study, Printing and Publishing Office, National Academy of Sciences, 2101 Constitution Ave NW, Washington DC 20418, \$6.95.

A must to avoid

would require between 2 and 4 times that amount, the Academy committee reckons. That would require about 500 new fertiliser plants, at a cost of some \$50,000 million at today's prices. Such a vast use of fertilisers would not only be inordinately expensive, but it would also lead to environmental problems through run-off into streams and rivers. Hence the importance of efforts to produce crop plants which can fix their own nitrogen.

It has long been known that leguminous plants have a symbiotic relationship with bacteria living in their root systems which fix nitrogen from the atmosphere and supply it to the plant in a usable form. The immediate goal of research efforts is to improve that symbiotic relationship, thereby increasing yields of leguminous crops without increasing the application of fertilisers. In the more distant future, research efforts are aimed at inducing similar symbiotic associations between bacteria and cereal plants and, perhaps, transferring the genetic capability to fix nitrogen directly into the cells of crop plants.

Each of those goals requires fundamental biological breakthroughs, however, and they may also involve ecological problems. Though researchers are optimistic, there's no guarantee that the required breakthroughs will be forthcoming. The Academy committee recommends a major boost in funding.

The second key effort, boosting photosynthetic efficiency, also requires substantial breakthroughs. At present, most crop plants capture only about 1-3% of the solar energy they receive, but some plants, such as corn and sugarcane, do much better. Such plants seem to possess a natural mechanism for suppressing the light-aided consumption of stored foodstuffs, and the hope is that research into the underlying processes will lead to methods of increasing the photosynthetic efficiency

of other crop plants. The potential is vast: the Academy report reckons that yields of some crops could be boosted by between 50 and 100% if the research produces results. The report therefore recommends a substantial boost in funds for such research.

Although those two efforts undoubtedly provide the major hopes for a technological fix for increasing food supplies, they are both long-term, long-shot efforts. Less glamorous projects, such as improved plant breeding, soil management and pest control are likely to be more certain and yield quicker results: they should thus be pursued equally vigorously, the committee states.

Increased social research

In the long run, social and organisational changes are likely to prove just as important as technological innovations in alleviating world hunger, and thus the committee urges a sharp increase in social research. In particular, noting that countries with such diverse social and political systems as Taiwan, the People's Republic of China and Sri Lanka have managed to increase food production while lowering birth and death rates, the committee recommends a programme of comparative analysis to see whether any generalisations emerge. "Social science research on food and nutrition lags significantly behind that of biological research because of shortages of skilled personnel, suitable methods of research, data, prior research findings, research funds and effective organisation", the committee states.

Ultimately, political and social changes to combat poverty are likely to be the most effective means to reduce hunger. They are, however, less easy to achieve than changes in the technology of food production. The Academy is nevertheless relatively sanguine about the prospects. □

The Academy committee's report calls for a sharp increase in agricultural research on food production and social research on food and nutrition policies. A large proportion of the effort will probably have to be undertaken in the affluent countries, particularly in the United States, but the committee urges that steps be taken to build up the research capacities of the developing countries, and that the international network of research centres be strengthened and expanded. The chief recommendations:

- Research spending on food and nutrition problems should be increased by \$210-230 million a year in the United States. A large share of the increase should go to the Department of Agriculture, whose research budget is now about \$700 million a year. The National Science Foundation, the National Institutes of Health and the Agency for International Development should also be given large increases in their research support.

- A new programme of competitive research grants should be established in the Department of Agriculture for work on basic problems such as increasing photosynthetic efficiency and biological nitrogen fixation. (The Ford Administration in fact proposed that \$28 million be spent on such a programme in fiscal year 1978, but the House Appropriations Committee recently reduced the amount to \$10 million.)

- A new post should be established in the Department of Agriculture with responsibility for research and education.

- The United States should train more researchers from developing countries and provide more direct support for establishing facilities and research institutions in developing countries.

- Two new responsibilities should be added to the Executive Office of the President: an office to develop and maintain a coherent strategy for dealing with world food and nutrition problems, and another to coordinate US and international efforts (in fact, such tasks will probably be given to the Office of Science and Technology Policy.)

The committee briefed White House officials on the recommendations last week and, though the reception was said to be sympathetic, the discussion concerned bureaucratic problems in the Department of Agriculture rather than research strategies.

Harrison Brown, committee coordinator

Towards a pollution policy

Richard Sandbrook outlines how a UNEP plan could help to save the Mediterranean from pollution

THERE are many indicators that the so-called environmental debate has moved on from its more sensational phase into a new and more difficult stage of human endeavour, at least as far as pollution questions are concerned. The catch phrases—'limits to growth', 'spaceship Earth', 'the environment revolution'—do not excite the media or its readers any more, much less governments. Anti-pollution legislation is no longer pushed through the world's parliaments, the UN or the EEC on a wave of public alarm and high idealism. It is becoming increasingly necessary to present solid scientific evidence of harm and an economic evaluation of benefits and costs before controls gain political support.

This trend is becoming evident in certain sections of the United Nations Environment Programme (UNEP) too. Born in Stockholm in 1972 on a crescendo of 'environmental' enthusiasm, it is now struggling to survive in the harsh world of international law, inflation-prone economies and hard scientific evaluation. But in one area at least UNEP has made this shift successfully. Its Mediterranean Programme is one of the most complex international pollution control and environmental protection exercises ever undertaken. It reinforces the trend toward regional rather than global approaches to environmental protection—at least for the marine environment; and it helps to marshal together many of the previously competing UN agencies, governmental institutions and independent research units that can play a role.

Intergovernmental consultations on the programme started in February 1974, with the Food and Agricultural Organisation (FAO) meeting on the protection of living resources from pollution. UNEP became involved that year and in February 1975 convened an intergovernmental meeting in Barcelona on the general protection of the Mediterranean. The gathering discussed the first draft of a framework or 'umbrella' convention for the protection of the Mediterranean, and approved a three-part programme encompassing legal arrangements, scientific research and monitoring and integrated planning for the region.

A year later, in February 1976, the umbrella convention was finally approved by 16 of the 18 Mediterranean

states (the exceptions being Algeria and Albania), together with two specific protocols attached to it on the prevention of pollution by dumping (ships and aircraft) and on intergovernmental co-operation in the event of a pollution emergency. The convention was very broad, committing states to "take all appropriate measures . . . to prevent, abate and combat pollution of the Mediterranean Sea area and to protect and enhance the marine environment". A signed convention is far from a ratified convention, however, and a ratified convention is in turn far from a working one. The 1969 amendments to the IMCO 1954 oil pollution convention, for example, only came into force after the required number of ratifications in January of this year; it will be a further year at least before it is working.

Will the Mediterranean agreements suffer the same fate? One suspects not, for the convention and the two protocols to date are but a part of the much wider environmental programme—driven on, in the northern Mediterranean at least, by the threat of reduced tourism, waterborne health risks and highly contaminated marine life locally. In March 1975, for example, the French Institute of Medical Oceanography issued a warning that if mercury pollution continued at its current rate then fishermen and others who consumed on average two kilos of certain local fish a week would be chronically ill within 7 years and dead in 20 from mercury poisoning.

The legal arrangements, for example, are not going to end with ratification of the three existing instruments. A further protocol on land source pollution could be ready by the end of 1977 to be added to the framework convention, and a further protocol on exploration and exploitation of the seabed and the continental shelf is planned.

Questioning the rationale

The rationale for this grand plan, at least on an international level, is often questioned. Why not leave pollution control up to individual states or at most neighbouring states? Is it simply following a fashion set by the Oslo and London dumping conventions and the Paris convention on land source pollution? Or do the coastal states really believe that an integrated and regional approach is necessary?

The geography of the region provides some explanation. The Mediter-

anean Sea is a semi-enclosed sea and its water is effectively divided into two basins (north and south) which rotate cyclonically. In this way pollutants cross national frontiers; those from Italy potentially affect France, and those from the Nile Israel. The currents hug the coasts and such ship-source pollutants as floating litter and tar tend to be spun centrifugally toward them. Saline water enters the sea in the surface waters of the Straits of Gibraltar and leaves by the same route at greater depth. The average estimated residence time of the water is of the order of 80 years, although the range is probably from a few to several hundred years. This in effect means that for those long-lived and stable pollutants accumulation over time is bound to occur.

Secondary to the transfrontier rationale is the monitoring and research needed to underpin environmental controls. Given that the first step in controlling any pollutant is to know its source, its concentration and then its effect, the idea of monitoring the sea as a whole for the three sets of variables makes eminent good sense politically and for the more mobile and persistent pollutants good sense scientifically. This monitoring work is now progressing on seven fronts throughout the Mediterranean basin:

- Baseline studies and monitoring of oil and petroleum hydrocarbons, in conjunction with the Intergovernmental Oceanographic Commission of UNESCO and the World Meteorological Organisation. This programme, which now involves 11 of the 16 coastal states and 26 national laboratories, is focused on the new regional oil combating centre in Malta, which is run by IMCO.

- Baseline studies and monitoring of the heavy metals, particularly mercury and cadmium in marine organisms—a project sponsored by FAO and UNEP in 14 countries and 38 laboratories.

- Baseline studies and monitoring of DDT, PCBs and other chlorinated hydrocarbons—an FAO/UNEP project in 13 countries.

- Research on the effects of pollutants on marine organisms and their populations (FAO/UNEP in 11 countries). The aim is to study the effect of various pollutants on the population dynamics of certain test organisms; it is hoped the study will lead to the identification of particularly vulnerable species

*The 1972 Oslo Convention for the Prevention of Marine Pollution by Dumping from Ships and Aircraft entered into force in 1974 and covers the North Sea and the northwest Atlantic. The London Convention is a global convention to control the dumping of wastes at sea, and entered into force in 1975; it is now administered by IMCO. The Paris Convention for the Prevention of Marine Pollution from Land-based Sources covers the same area as the Oslo Convention and is not yet in force.

A moving conference process: how nearly all the Mediterranean states and the various UN agencies are coming together before the intergovernmental meeting on the protection of the Mediterranean in November 1977.

within the different tropic levels at various stages of their life cycles and in time lead to the identification of indicator species for water quality criteria.

- Research on the effects of pollutants on marine communities and ecosystems (FAO/UNEP in 12 countries). The project will amount to the intensive field study of various coastal ecosystems under stress, or of areas where ecosystem changes may be anticipated as a consequence of development and areas that are unpolluted and designated as marine parks for control purposes.

- Problems of coastal transport of pollutants (IOC/UNEP in 12 countries). The aim is to study the water circulation in coastal areas to understand better the physical transport of pollutants.

- Coastal water quality control (WHO/UNEP in 8 countries). The overall objective of this pilot project is to produce statistically significant data on pollution levels that may affect human health.

Each of these seven projects involves a nominated 'activity centre'; also needed is the back-up support of the IAEA and UNEP on intercalibration of equipment and analytical techniques and the provision of common maintenance services for the more sophisticated laboratory instruments. A technical training programme is under way; grants for instruments and a growing number of manuals and guidelines for the participating laboratories are available.

All of this will be the backdrop against which the next protocol will emerge. It will take a form broadly similar to that adopted in Paris in 1974 for the North East Atlantic, in Helsinki in 1974 for the Baltic Sea Area and in Brussels in 1976 for European Economic Community waters. As it is being drafted midway in the seven point scientific programme, however, the hope is that after a series of evaluation meetings of the projects involved, it will avoid some of the pitfalls that the precedents have fallen into. For example, the interim body set up to help the process of ratification of the Paris convention (IPARCOM) is the arena for much disagreement. Typical questions to be answered are: What constitutes pollution? What should be monitored? And by whom and where? For the convention simply states that by pollution is meant substances or energy introduced directly or indirectly by man that results in such deleterious effects as hazards to human health, harm to living resources and marine ecosystems, damage to amenities or interference with other legitimate uses of the sea. What is meant by 'hazards', 'harm' and 'interference' is unclear.

And on top of the work of IPARCOM (and any Mediterranean protocol developed) are the problems imposed by the European Commission directive on land source pollution (1976).

Black and grey lists

Both the Paris convention, and its later brother, the Brussels directive, include two lists (as annexes) of substances to be considered. The so-called black lists in the Paris convention relate to substances to be eliminated from the environment—for example, mercury and its compounds, persistent oils and hydrocarbons of petroleum origin, cadmium and cadmium compounds—and in the Brussels directive a similar list which is to be subject to uniform emission standards with an option for states to operate as-yet-undefined "environmental quality objectives". In both there are grey lists of substances that will be subject to less strict controls.

The treaty language is always, of course, strong enough to sound impressive environmentally—even, as some would allege, economically. One admitted purpose behind the Brussels approach is that all states should suffer the same environmental constraints no matter where the pollution occurs—an 'equalising' of competition. But in practice things are far from simple. There is little or no quantitative evaluation of acute or chronic harm to back any standards that may be set, and no recognition of the fact that receiving environments differ. For those who want to delay ratification this provides excuse enough. But a less cynical view is that unnecessary controls are not in anyone's interests other than the pollution control equipment manufacturer—and so why have them? The British have become so upset by the arguments over Paris and the Brussels directives that they have now resorted to publishing a detailed explanation of their case (DoE Pollution Paper No 11).

This time round, Mediterranean governments who have been involved in the EEC and IPARCOM process should have an idea of the likely costs involved, the necessary levels of control that should be applied and most particularly be able to avoid the problems of definition that bedevil the precedents in the field. Not least, by having some research first, many more governments will be aware of just what is under consideration.

The final concern of the programme is that of integrated planning; here the so-called Blue Plan and the Priority Action Programme are the two components. Throughout, UNEP has been at pains to stress that it is not posturing as an executive agency for the area—a sort of unofficial Brussels for the Mediterranean basin—and the Blue

Plan reflects this. There are no 'line' responsibilities envisaged but a set of 'processes' to be developed to enable governments to take the environment into account when making their own decisions. Thus systematic surveys of all major economic growth areas are called for, and so are studies of such varied topics as soil protection, water resources and urbanisation trends. The Priority Action Programme is in essence a part of the same plan but it includes areas ready for immediate action before the overall process gets underway. Again a series of cooperating national and international agencies are included.

The catch, of course, is how much notice governments will take of the environmental advice that they receive, and to what extent the whole effort will become bogged down in regional economic disparities. It all looks dangerously like the European Commission but without the teeth of its Council. To a certain extent, governments will become locked into a process that will ensure compliance—the major aid agencies (UNDP and the World Bank) that are helping some of the southern coastal states are going to be influenced by the development criteria agreed under the plan's auspices. Similarly, FAO who are developing the fisheries and WHO who are helping to build up sanitation infrastructures in the southern states are going to be closely involved. However, both components are small in resources. The first phase, costing an estimated \$1.5 million in total will, one suspects, be little more than an exchange between planners and development strategists.

This is not to knock too much. It is after all remarkable that Greece should sit with Turkey—Israel with Egypt—and talk over such important domestic strategies at all, and if the approach of the Mediterranean programme goes well it is likely to spread to other regional waters—the Persian/Arabian Gulf, the Caribbean Sea and the West African coastline for example.

There is no doubt that the unified scientific monitoring will lead to progress first in our understanding of the marine ecosystem and maybe then in controlling the obvious pollution that is going on. Governments are discovering disturbing levels of heavy metal contamination and waterborne disease in their waters. These facts are going to be made public one day and that is going to ensure a change in the level of investment and control exercised. Cousteau, who in 1972 said that the Mediterranean would surely die, admits that much progress. In 1976, he sent a telegram to UNEP saying that it might live after all. □

GENETICS

Full circle

The debate over potential hazards associated with recombinant DNA experiments has now turned full circle in the United States, with many of the people who first raised the issue in public arguing that legislation is unwarranted. Colin Norman reports

EXACTLY four years ago, a group of scientists attending the 1973 Gordon Conference on nucleic acids began to worry for the first time about the possibility that transplanting genes from disparate species into living viruses or bacteria might produce an organism with potentially hazardous properties. Discussions at that meeting led to a resolution calling for an investigation of such concerns, and the recombinant DNA debate has been picking up momentum ever since. Last week, at the Gordon Conference, some of the same scientists expressed alarm at where the debate has led.

An open letter, signed by 137 scientists at the conference—more than 75% of the attendees—warns that legislation now pending before Congress and before some state and local authorities in the United States could cripple recombinant DNA research. The letter claims, moreover, that the impetus behind the legislation comes from “exaggeration of the hypothetical hazards of recombinant DNA research that go far beyond any reasoned assessment”.

The Gordon Conferences are attended by scientists who are actively engaged in research on nucleic acids, and they thus represent people who would be directly affected by legislation. Their concerns are therefore not entirely devoid of self-interest, but they nevertheless probably reflect the views of a large proportion of the scientific community.

The call for a halt to legislation is, however, too late to have much effect and it could even be counter-productive. Committees in both the House and the Senate have now approved versions of legislation to regulate recombinant DNA research in the United States, and there is now strong and unstoppable momentum behind the legislative process. Moreover, there is a compelling argument for legislation: guidelines now governing federally-funded recombinant DNA research, issued last year by the National Institutes of Health, are not legally enforceable and do not formally apply to research supported by non-government sources.

The chief concern which led to the

formulation of the open letter at the Gordon Conference is that the legislation is likely to go well beyond simply putting the NIH guidelines into legal regulations. A bill approved by the Senate committee on human resources would establish an 11-member Presidential commission to regulate the research, for example, while a bill approved by the House health subcommittee would set up a complex procedure for approving some types of experiments on a case-by-case basis. Both versions call for new regulations to be drafted, and both would also impose stiff penalties on people caught flouting the rules.

The open letter claims that “the experience of the last four years has not given any indication of actual hazard”, and a number of scientists have recently testified before Congress that research indicates that the hazards may be much more remote than first thought. Such claims rest on evidence that there may be greater natural genetic exchange between species than once believed, that genes from higher organisms have not so far been found to be faithfully expressed in bacteria, and that bacteria bearing transplanted genes seem to be less capable of surviving in the environment than unmodified bacteria. The authors of the letter therefore suggest that while the hazards seem to be growing less plausible, controls on the research are getting more strict.

Nevertheless, few scientists are willing to argue that the research is entirely devoid of risk and thus should not be controlled. Moreover, opponents of the research have also

pointed out in Congressional testimony that evidence suggesting that the risks are less plausible is very preliminary, and that there is no justification for lessening the controls. Faced with those circumstances, Congress is not likely to drop its moves towards legislation because those most affected believe that strict legal regulations are unjustified.

The authors of the letter in fact tacitly concede that Congress is bent on legislation, and they thus urge that “should legislation . . . be deemed necessary, it ought to prescribe uniform standards throughout the country”. The idea is that Congress should prohibit state and local governments from setting their own controls on recombinant DNA research, but Congress is again unlikely to accede completely to the request. Both versions of legislation now under consideration would allow local authorities to set regulations which are at least as strict as the federal controls, but the local authorities would first have to prove that their additional restrictions are required to protect public health or the environment.

A few months ago, a number of prominent scientists reluctantly agreed that legislation is needed to ensure that controls on recombinant DNA research are applied equally to experiments funded by government or private funds. They also supported legislation on the grounds that it would stop local governments from setting their own controls. “Scientists were once urging Congress to pass legislation, and now they are telling us that legislation is unnecessary”, complained one Senate staff member last week. “That is not likely to help their case”. □

Open letter

The open letter signed by 137 scientists at the Gordon Conference reads:

“We are concerned that the benefits of recombinant DNA research will be denied to society by unnecessarily restrictive legislation.

“Four years ago, the members of the 1973 Gordon Conference on Nucleic Acids were the first to draw public attention to possible hazards of recombinant DNA research. The discussions which started at that meeting resulted in the issuance in 1976 of the NIH Guidelines for the conduct of this research.

“We, members of the 1977 Gordon Research Conference on Nucleic Acids, are now concerned that legislative measures now under consideration by Congressional, state and local authorities will set up additional regulatory machinery so unwieldy and unpredictable as to inhibit severely the further development of this field of research.

We feel that much of the stimulus for this legislative activity derives from exaggerations of the hypothetical hazards of recombinant DNA research that go far beyond any reasoned assessment.

“This meeting made apparent the dramatic emergence of new fundamental knowledge as a result of application of recombinant DNA methods. On the other hand, the experience of the last four years has not given any indication of actual hazard. Under these circumstances, an unprecedented introduction of prior restraints on scientific inquiry seems unwarranted.

“We urge that Congress consider these views. Should legislation nevertheless be deemed necessary, it ought to prescribe uniform standards throughout the country and be carefully framed so as not to impede scientific progress.

“The 137 undersigned are members of the 1977 Nucleic Acids Gordon Conference”.

SEVESO

Roche's reply

The debate continues on the Séveso disaster. Alastair Hay reports

In an effort to counter the criticism of its subsidiary Givaudan, the Swiss multinational pharmaceutical company Hoffman-La Roche has recently given wide publicity to an internal newsletter on the environmental hazards at the Italian town of Séveso. The town was contaminated on 10 July last year by an explosive discharge from a chemical reactor manufacturing trichlorophenol. The discharge contained an extremely toxic contaminant, dioxin.

Over the past few months many press, radio and television reports have referred to the deteriorating position at Séveso. These reports quite naturally directed attention to Givaudan, the owners of the Icmesa chemical plant responsible for the contamination problem, and have been extremely critical of the company. The Roche newsletter represents an attempt on the behalf of its subsidiary to redress the balance. It claims to produce as objective an account as possible of the picture at Séveso, speaking of "considerable progress" made in the decontamination effort and the settlement of private compensation claims, and it refers to the "encouraging" health situation.

But the newsletter is primarily concerned with the prevailing position, referring only in passing to the circumstances of the actual 10 July accident. The reactor's explosive discharge is referred to as a toxic mixture of chemicals which escaped from the plant "as a result of a runaway reaction". As the cause of the accident is the subject of a legal inquiry by an Italian court, Givaudan obviously prefers not to make public pronouncements about the case.

In private, however, a company spokesman maintains that even after months of tests they still do not know what caused the accident. Givaudan can hardly deny that its Icmesa plant was the cause of the problem, but the company denies vehemently the suggestion that it was in any way negligent. "Human error" is mooted as the probable cause of the explosion.

Company officials insist that Givaudan knew of the previous accidents in trichlorophenol plants—at least nine have been publicly documented since 1949, and it is thought there may have been as many as 14. The officials say Givaudan accordingly designed the plant to incorporate safety

features to protect employees. This meant that the safety valve and vent pipe were placed to discharge the reactor contents away from the confines of the factory—with the disastrous consequences that the July accident demonstrated. The company now admits that there may have been a "lack of foresight" in anticipating this event.

In response to accusations that the company withheld information on its reaction processes, Givaudan insists that it had all the necessary permits authorising operations on the site. As for the trichlorophenol reaction, dioxin production was constantly monitored and ranged from 10–30 ppb, well below the level recorded in other plants producing trichlorophenol destined for the manufacture of the herbicide 2,4,5-T.

The company maintains that two weeks was necessary to assess the extent of the contamination in the Icmesa neighbourhood after the accident, but that as soon as reliable data was to hand, it was passed to the Italian authorities.

One of the principal problems facing the Italian authorities and Roche was the paucity of clinical information on dioxin toxicity in humans. Dr Giuseppe Reggiani, director of clinical research for Roche, says the health situation at Séveso is "reassuring". He insists, however, that certain categories of high risk groups, in particular the children with chloracne and the residents of the heavily contaminated Zone A, be constantly monitored as part of an epidemiological survey.

The Lombardy regional authority is to undertake such a survey under the auspices of its Health and Epidemiology Commission. The commission proposes to measure some 22 biochemical parameters in a population they consider likely to have been in contact with dioxin. The authority expects Givaudan to pay for the operation. The company, on the other hand, insists that before government claims can be met, due weight will have to be accorded to one of their decontamination proposals, made in August of last year. This proposal was not accepted by the Italian authorities, but would have involved the spraying of vegetation with an olive oil-cyclohexanone mixture, which would have facilitated the photoreduction of dioxin present. Givaudan claims that its programme could have resulted in the destruction of 80–90% of the dioxin.

BRITAIN

Down wind

WITH the publication last week of a 70-page report on wind energy*, the UK Department of Energy (DEN) has now completed its first round of studies on alternative energy sources. Responding to a question at a press conference last week to introduce the report, the department's chief scientist, Dr Walter Marshall, said it was "unambiguously clear" that the source which was "top of the pops" was wave power. That was followed by solar power, then geothermal and tidal power.

Final judgment, according to the head of the DEN's Energy Technology Support Unit at Harwell, Dr K. Dawson, would depend on economic and environmental considerations as well as potential contributions to total energy needs. But it was clear, he said, that wind wouldn't solve the country's energy problems. Marshall himself accorded it low priority because, he said, he has doubts whether it will be environmentally satisfactory.

That small dampener does not mean the DEN is not going to pursue the matter. The department and an industrial consortium are each pitching £75,000 into what is called a "detailed design study for a large machine installed on a prime site"; another £10,000 is coming from two interested Scottish utilities. The idea is to obtain a firmer estimate of costs, to improve the confidence with which the current cautiously optimistic estimates are held.

But, as Marshall sees it, there is a problem. If it is environmentally acceptable to use the 3,000-odd identified sites and it is possible to put aerogenerators on them, the costs might be reasonable and wind energy might seem economic even now at current prices. But, he goes on, if there is less confidence about the sites and it is left to the market to introduce wind power, the number of sites used would be small, costs would be high and wind power would hardly be economic.

Last week's report was completed before Sir Martin Ryle, the Astronomer Royal, detailed his arguments favouring wind power in an article in *Nature* on the economics of alternative energy sources. Asked whether Ryle's arguments would be incorporated into DEN work, Marshall said that, now the DEN had finished its own calculations, he was trying to get people together, including Ryle, to see what should be done next.

Marshall's personal view, that economic debate lies somewhere between resolvable disagreement on technological fact and irresolvable disagreement on religious theology, leads him to look for agreement on what should be done to resolve uncertainties. Hence his own preference, amply demonstrated in the case of wind power, for a systematic step-by-step scaling-up approach—a view which, as he points out, also goes down well with the Treasury.

Chris Sherwell

*The prospects for the generation of electricity from wind energy in the United Kingdom, Energy Paper Number 21 (HMSO, £2.25)

URANIUM

Solidarity and optimism

The Uranium Institute held its second annual meeting in London last week. Chris Sherwell reports

IT HAD been a busy year since members of the Uranium Institute last gathered in the splendid London facilities of the Institute of Electrical Engineers. The uranium cartel controversy had blown up. Anti-nuclear forces had made headway. And a new US nuclear policy had emerged. But if most of the more than 200 delegates who attended last week's meeting came somewhat chastened by the events of the previous twelve months, after two days closeted together they seemed to leave in slightly more buoyant mood.

A renewed feeling of solidarity was perhaps an inevitable outcome, but the sense of optimism that emerged from the usual business of exchanging ideas and informally discussing recent developments was a bonus. That optimism was expressed by Terry Price, the Uranium Institute's secretary general, when in summing up the formal symposium on uranium supply and demand he offered his 'scenario' for the immediate future.

Once it was appreciated that numbers mattered and there was agreement on the facts, he said, the realisation

that there are no easy answers would see the reinstatement of nuclear power to respectability. The current debate would be damped down, a large programme of thermal reactor building would go ahead and the industry's long lead-times would see a determination to push ahead on both fast breeders and reprocessing. The lasting legacies of the present period of uncertainty would be "wholly beneficial", not least the political legacy of a heightened awareness of the need to deal with proliferation.

Earlier the symposium had ranged over the most general and most specific problems relating to uranium and nuclear power. An opening paper examined projected energy requirements to the year 2000, and found that even in a 'world of internal contradictions' (rather than a 'belle époque') there was a large role for nuclear power. Later presentations discussed exploration techniques and factors affecting mining costs. Between these extremes came the most controversial issues—those of supply and demand and of proliferation—and here the real uncertainties arose.

On supply, for example, one paper on the US position contended that unless "drastic action" was taken, "there is not sufficient uranium forthcoming to

sustain a nuclear industry based upon light water reactors". That contrasted with the optimistic assessments of the Ford Foundation report which is apparently the basis of US policy. Another paper on the same subject reveals some of the findings of a US National Academy of Sciences panel; these all indicate serious supply shortages in or beyond the mid-1980s.

Supply questions easily spilled over into proliferation matters. Anthony Grey of Pancontinental Mining suggested that the US emphasis on international safeguards meant that Australia, by using its influence as a major uranium supplier, could lessen rather than increase the risk of nuclear war. Kyoji Mizumachi of the Tokyo Electric Power Company was more critical of the effects of the US anti-proliferation stance: this "drastic change of policy had been a 'great shock' to Japan. And Terry Price himself took the opportunity to criticise an erudite defence from Harvard lawyer Abram Chayes, suggesting that other countries would not alter their energy strategies without being convinced by their own advisers—and the said Price, would be giving cautious advice. One speaker's conclusion sounded most appropriate: at the moment no quantitative conclusion about the impact of proliferation policies on the uranium market can be drawn.

COMECON

Energy supply problem?

The 31st session of the Council of Mutual Economic Assistance (Comecon), held in Warsaw last week, reflected a growing concern of the eight member countries with raw materials and energy. Vera Rich reports

TO DATE, developments in the fields of raw materials and energy have largely been based on the 'unlimited' supplies of the Soviet Union. According to official doctrine, delays in the supply of these resources have been essentially a matter of logistics; so when the smaller Comecon members want immediate access to these resources, they have to contribute to the cost of development.

Now, however, although the speeches in Warsaw still stress the dependence of members countries on Soviet supplies, there is a tacit recognition that the Soviet Union cannot at present meet the total demands of the bloc. While acknowledging the "decisive

importance" of Soviet supplies, the Hungarian Premier, György Lazar, for example, stressed the need "to fully utilise the resources of the member countries"; he noted that Hungary was stepping up the pace of research into fresh domestic resources of fuel and raw materials. And Manea Manescu of Romania announced a massive cutback in the use of hydrocarbons for power purposes, so that they may be devoted primarily to the petrochemical industry.

The simple answer to the energy problem seems to be nuclear power. Vaclav Hula, the Czechoslovak representative to the Comecon Committee for Cooperation in Planning, put forward plans for the development of atomic power plants which would more than double the nuclear capacity of the Comecon bloc in each successive five-year plan. The final communiqué says the "session particularly stressed the importance of the programme for the maximum development of nuclear engineering of the Comecon countries

in providing a comprehensive solution of issues related to the development of the atomic power industry, and a solution to the entire problem of fuel and energy".

The communiqué recommended that an agreement on multilateral international specialisation and cooperation in the production and delivery of atomic power station equipment for 1981–1990 should be concluded next year. No formal reference was made to the potential hazards of a major nuclear programme, and the only reference to the environment was in a list for suggested inter-state conferences that would lead to "constructive business cooperation" with the capitalist countries. The Carter nuclear policy was not, apparently even mentioned.

A major conversion to atomic power has long been a principle of Comecon energy policy, which is not hampered by ecology-minded minority pressure groups. The new resolution, therefore, is not so much a change in policy, as a recognition that it is time to proceed from theory to practice.

IN BRIEF

Windscale contract details

In the second week of the Windscale inquiry in Britain, during the whole of which BNFL's managing director, Mr Con Allday, remained on the stand, further details of the proposed deal with Japan to reprocess spent oxide fuel emerged. Having earlier given sight of the proposed contract, BNFL published a summary of the terms detailing the amount of fuel involved (1,600 tonnes), the Japanese payment of development costs (£150 million) under the 'cost-plus' arrangements, and the value of the contract to BNFL (£400 million).

An official of the French reprocessing firm COGEMA, speaking at the Uranium Institute meeting last week, gave details of French reprocessing plans and listed the conditions attaching to the 'cost-plus' type of contract that COGEMA and BNFL have developed to fulfil "social and political requirements". These were: no financial

risk for the reprocessor in reprocessing foreign fuel; an advance from the utility of its share of the total plant investment in the form of prepayment for reprocessing services; and a contractual agreement, backed by an understanding between governments, giving the option of returning waste to the country of origin for final storage in an agreed form.

Whale quotas announced

At its Canberra Conference last week, the IWC announced the largest cutback in the number of sperm whales which can be caught in the North Pacific. It recommended a complete moratorium on the killing of male sperm whales in the area and set the quota for females at 763; the equivalent figures adopted for this year were 4,320 and 2,800 respectively. As the North Pacific is the main whaling ground for the USSR and Japan, the two countries may find it no longer economic to

keep their whaling activities going in the area. Under the IWC's rules, however, objections to decisions can be raised up to 90 days after the conference and Japan and the USSR are expected to do this.

Although some conservationists thought the cutbacks were as favourable as could be expected, others feared that the IWC's reductions for next year were an indication of mismanagement in previous years: overwhaling had meant that stocks were now very low.

Marshall move

Dr Walter Marshall, chief scientist at the UK Department of Energy, is to leave his post and resume full time work for the UK Atomic Energy Authority. An announcement this week from the Minister, Mr Benn, says this is in view of the UKAEA's significant role in forthcoming important nuclear decisions.

JUDGED by results, the Viking's journey to Mars last summer was an enormous success. Not the least of the wonders was successfully putting down both the landers by programmed automation, virtually blind-fold, among rocks large enough to topple them. These obstacles were too distant to be perceived in the images received on Earth before the descent started. The final 30 kilometres of drop lasted only 5 minutes. Six kilometres above the surface, the parachute blossomed out, unseen in the thin and ghostly atmosphere of Mars. Retro-rockets were ignited that pushed backwards against gravity, the lander settled gently on the surface, and its camera had taken a picture of the terrain before anyone learned of the landing. Automatic instruments chattered out the news by radio waves that took 20 minutes, at the speed of light, to get back to huge dishes, poised 350 million kilometres away in Australia, Spain and California, scooping up the incredibly faint signals.

The news was not of little green men, but of nitrogen, oxygen, krypton and xenon, of the exact temperature, and of a reddish magnetic dust on the surface. But it was the pictures of the barren, rock-strewn landscape with the metal footpad of the lander in the foreground, that spread the tidings most dramatically all over the world.

Incredibly, all the complex instruments were in working order in both landers except for one seismometer. Martian soil was scooped up and tested for life by three procedures.

The first (gas exchange) measured changes in the gas above a sample of soil moistened with a rich culture medium. The Martian soil im-

Mission to Mars

THOMAS H. JUKES

mediately released some oxygen (surprise number one). The second procedure (labelled 'release') looked for production of radioactive gas from a culture medium containing radioactive nutrients. There was rapid evolution of such gas when a fresh soil sample was added to the medium.

The third test shone a light on untreated, unmoistened soil in presence of $^{14}\text{CO}_2$ and ^{14}CO for 120 hours. The

soil was then pyrolysed and the gases that escaped were examined for products of photosynthesised organic matter. The first result was positive, although weakly so. But later experiments showed that preheating the soil to 90° for nearly 2 hours had no effect on the reaction, so the experimenters concluded "... it is unlikely the reaction is biological".

And so the initial feelings of gratification and excitement became tempered with wonder and mystification. We had steeled ourselves for negative findings (a cat without a grin), but we had not expected atypical and perhaps non-biologically positive results (a grin without a cat). The absence of the cat was underscored by negative results in tests for organic compounds in a fresh sample of soil carried out with an extraordinarily delicate 'gas chromatography mass spectrometer'.

The other instruments in the Vikings have sent a wealth of information on Martian climate, geology, meteorology and elementary composition. The North polar cap is now known to be ice. The atmospheric analysis agrees with a concept expressed by one scientist that the cap may be the tip of an iceberg; the rest of the ice is covered with Martian soil.

And so the Earth spins on its orbit delicately poised between the sterile inferno of Venus and the cold and dreary desolation of Mars. We are just the right distance from the Sun to be the planet of harvest, dew and rain; the source and abode of life, unnumbered as the sand.

correspondence

Science and ideology

SIR,—As a typically naive graduate student, I have tended to assume that science should be pursued in a rational and objective fashion and that ideology and political viewpoint have little effect on the scientific truth of a subject. Admittedly, this view stands in contradistinction to the dialectical materialism of Marxism as interpreted by Lysenko, but I have been thoroughly impressed by the advances in human knowledge that have occurred during the past several centuries using Francis Bacon's inductive approach to scientific reasoning.

At any rate, while at the recent annual meeting of the Biophysical Society in New Orleans I noticed that Dr Schwartz had organised a forum 'Racist and sexist implications of sociobiology' (note how the title is free of any ideological predisposition involving connotative and pejorative adjectives). Owing to other commitments, I missed the talk by the geneticist but I did arrive in time to catch the talk by the representative from the Boston Committee Against Racism (which I later decided should be more aptly named the Boston Committee Against Intellectual Freedom).

I had, again in my naiveté, hoped for a rational presentation of the reasons that sociobiology might be on weak scientific grounds. Instead, the talk began with the speaker admitting that he was not an expert in the area and then continuing with the unqualified assertion that the material in Edward O. Wilson's book, *Sociobiology: The New Synthesis* (1975, Harvard Press), was not scientific with the implication that no respectable scientific journal would publish such material. One of his principle objections to the theory was its use of what the speaker termed "anthropomorphism of non-human animals and insects", which, when one cut through the persiflage, meant that he strongly objected to extrapolating observations on hereditary characteristics of insects and animals to man.

It is worth noting that Lysenko used the exact same justification for outlawing medical genetics in the Soviet Union (you should see the verbal persiflage of Marxist rhetoric Lysenko used to 'prove' that human chromosomes could not exist). More mundanely,

some of my rural relatives here in Alabama use a similar rationale to 'prove' that evolution is false—God could not possibly create man along the same tree as other animals.

As the talk progressed, we were subjected to numerous emotive and pejorative terms such as racist, fascist, sexist along with the not-so-subtle hint that anyone who would view the subject from the standpoint of possible scientific validity had to be one of the above. (Reminiscent of the way that Lysenko characterised Soviet biologists who dared believe in Mendelian genetics as "enemies of the people".) The speaker certainly did not believe in a rational scientific approach but preferred to employ connotative, pejorative, obfuscatory, equivocal, circumlocutionary verbal persiflage (*sic*) that, while difficult to follow on a logical level, certainly sounded authoritative and proved even more difficult to refute. Under the circumstances, I can quite clearly see how the Eastern European IQ scare of the early 20th century is somehow related to the scientific validity of sociobiology.

Personally, I have no idea whether or not sociobiology will prove to contain elements of truth. However, I do not believe that one's ideological views are likely to change facts (even though the medieval church suppressed Aristotle's teaching for close to a thousand years because it disagreed with church doctrine). Certainly objecting to 'anthropomorphism' (the speaker's term) solely on the ground that it is objectionable flies in the face of the inductive process on which science is based. The proper approach is to make an extrapolation to man and then design experiments or search for data in an objective fashion that might prove or disprove the hypotheses involved. Unfortunately, I am not optimistic that this is likely to occur given the present political climate not only in the United States but worldwide. I am sure that any data obtained to support either the truth or falsehood of sociobiology, IQ testing or any of the related areas will be denounced by the other side—or in many cases buried under numbers and statistics from which one can, through convolution, draw one's own interpretation of the data (see Matters Arising, *Nature*, 266, 279–281; 1977).

Certainly the fact that the Bio-

physical Society would invite a speaker who was making such an overtly ideological attack speaks poorly for the organisers of the conference. I prefer to listen to my relatives in the rural Deep South discuss how evolution is a Godless bolshevik conspiracy and how Darwin was one of Satan's emissaries. Their tone is admittedly anti-intellectual, but at least it isn't ostentatiously pretentious. If one removes some of the intellectual facade from many of the ersatz scientific debates heard in the areas discussed in this letter, one will find the intellectual content comparable.

Yours faithfully,

WILLIAM O. ROMINE

Alabama, USA*

Israel's President

SIR,—Contrary to the belief expressed (9 June, page 486), the office of President of Israel has not always been occupied by a scientist.

The first President, Dr Chaim Weizmann, was a biochemist. He was the first reader in biological chemistry at the University of Manchester and later became Director of the David Seiff Institute at Rehovot—subsequently renamed in his honour.

The second and third Presidents, Itzhak ben Zvi and Zalman Shazar, were primarily both politicians of the establishment, although ben Zvi did do some sociological research on ethnic minorities among the Jews. Before becoming President, ben Zvi was known as a founder, with David ben Gurion, of the Histadrut—the trade union movement. Shazar for many years was a newspaper editor before entering politics and subsequently becoming Minister of Education.

Ephraim Katzir, the fourth and current President, is a biochemist of international repute. He is fortunate that the duties of office as President also enable him not to neglect his scientific career.

Perhaps the message which should be passed on is 'Biochemists Rule . . . OK!'

Yours faithfully,

B. SAMPSON

London, UK*

news and views

Contractile filament organisation, mechanics . . .

from John Squire

FEW people would question nowadays that most muscle types, including vertebrate smooth muscle, shorten by a mechanism involving the relative sliding of two principal muscle filaments, the thin actin filaments and the thick myosin filaments. The surfaces of the myosin filaments are covered with arrays of globular projections (the ATP-splitting heads of the component myosin molecules) and the relative filament sliding is thought to be due to the interaction of these projections (often called crossbridges) with the neighbouring actin filaments. It has been shown that virtually identical actin filaments (except for differences in length and the presence or absence of the regulatory protein troponin) occur in all muscle types and also that the thick filaments, although far from being identical, probably have their myosin projections or crossbridges organised into closely related surface arrays. An inevitable conclusion from these results is that the local crossbridge environments in all muscles are probably rather similar and that the basic force-generating mechanisms must therefore be similar too. Much current research on muscle is therefore aimed at answering two fundamental questions: 'how does the crossbridge interaction with actin actually generate force?' and, less obvious but equally crucial, 'what is the minimum organisation of actin and myosin molecules sufficient to form a viable contractile system?'. This latter question has become even more important in the light of recent fascinating discoveries of the presence of actin and myosin molecules in a bewildering variety of non-muscle cells (see Pollard and Weihing *CRC Critical Rev. Biochem.* **2**, 1; 1974). It now seems evident that many, if not all cells possess the ability to form rudimentary contractile systems involving actin and myosin and possibly that these systems comprise filaments which are formed spontaneously at different places and times as required by the immediate needs of the cell.

From studies of the molecular

arrangements of the ordered arrays of actin and myosin filaments in different muscles it has become apparent that a common organisational feature crucial to muscular contraction concerns the relative polarities of the interacting filaments. Although different muscles may involve slightly different polarity arrangements the structure of a sarcomere in striated muscle (Fig. 1) serves to illustrate the point. Here the myosin filaments are bipolar; the myosin molecules of each half of a filament point in opposite directions. The actin filaments are arranged so that those which interact with one end of a thick filament are of opposite polarity to those interacting with the other end.

Organisation

The organisation of filament polarity has been illuminated by a number of *in vitro* studies. For example it was shown by Huxley (*J. molec. Biol.* **7**, 281; 1963) that synthetic self-assembled myosin filaments with a bipolar structure can be prepared from relatively pure preparations of myosin. Bipolar assembly must therefore be an intrinsic property of the myosin molecules themselves. Similarly, self-assembled actin filaments can be prepared from actin solutions and these have been shown to be polar by labelling them with a preparation of isolated myosin heads (myosin heads which have been cleaved enzymatically from the rest of the myosin molecule). Such 'decorated' actin filaments show a characteristic 'arrowhead' polar structure, (Huxley *op. cit.*; Moore *et al. J. molec. Biol.* **50**, 279; 1970) which shows clearly that

Fig. 1 Highly schematic diagram of the organisation of polarities in a striated muscle sarcomere. The Z-bands (Z) define the ends of the sarcomere. (m is a myosin filament, a an actin filament). Polarity in the thin filaments is indicated by the arrow heads.

the two molecules need to be pointing in the right directions for their highly specific interaction to occur. Polarity organisation must therefore be a crucial requirement for a viable contractile system.

In a highly ordered muscle, such as a vertebrate skeletal muscle, one could speculate that the assembly of myofilaments might well be organised systematically during myogenesis by external factors so that, for example, actin filaments of the correct polarity are laid down at each end of the sarcomere. But it is not so clear that a comparable external mechanism could be involved in organising the filament polarities in spontaneously formed contractile assemblies in non-muscle cells.

Fortunately, in a recent study of actin/myosin self-assembly, evidence has been obtained which reduces the need to postulate an external factor in the assembly process. Hayashi *et al.* (*J. molec. Biol.* **111**, 159; 1977) have described the results of experiments in which globular actin molecules were added to a solution of synthetic myosin filaments to give a molar ratio of 2:1 and conditions were then altered so that the actin molecules polymerised into filaments. The structures which resulted were filament assemblies comprising bipolar thick filaments interacting at each end with thin filaments of opposite polarity; the latter presumably being defined by the myosin crossbridge polarity. These self-assembled contractile units are in many ways analogous to a small part of a muscle sarcomere with roughly six thin filaments interacting with each end of a thick filament. The only thing obviously lacking is a structure analogous to the Z-band to link the contractile units end-to-end.

Myogenesis is much more complicated, since there are many additional proteins in the sarcomere and, among other things, the thick and thin filaments have very precisely defined lengths. But these new results may show how spontaneous formation of relatively simple contractile systems might occur in non-muscle cells. Whatever the specific polarity organisation in the thick filaments this organisation may itself serve as a template for

ordering the polarities of the thin filament arrays. Since some of these non-muscle cells contain α -actinin, a protein also associated with muscle Z-bands, and presumably all the necessary regulatory proteins as well, it seems that most of the ingredients needed for the self-assembly of a simple contractile system may already be known. But one thing which is not clear from the new results is the actual mode of formation of the bipolar contractile units. The possibility favoured by Hayashi *et al.* involves the binding of actin monomers to myosin cross-bridges before actin polymerisation occurs. But the alternative, that actin polymerises and the resulting filaments then interact with the appropriately oriented end of a myosin filament, cannot be ruled out. A useful follow-up to this study would be to decide clearly between these alternatives possibly by determining the state of aggregation of the actin and myosin before polymerisation of the actin.

Crossbridge interaction

Turning now to the nature of the crossbridge interaction itself, equatorial X-ray diffraction evidence from vertebrate skeletal muscles and insect flight muscles has indicated that on activation there is a movement of mass, presumed to be the myosin cross-bridges, towards the actin filaments. Although attachment to actin probably occurs this has not actually yet been proved. Huxley (*J. molec. Biol.* **37**, 507; 1968) took the movement to be largely radial from the myosin to the actin filaments. On this basis the amount of mass transfer in active vertebrate skeletal muscle, calibrated against the transfer in rigor muscle in which actin labelling by 50 to 75% of the available myosin heads probably occurs, is about 50% of the rigor transfer (Haselgrove & Huxley *J. molec. Biol.* **77**, 549; 1973) or up to 80% (Matsubara *et al.* *Nature* **255**, 728; 1975). Cardiac muscle must be the most specialised of all the vertebrate striated muscles; it contracts rhythmically and is not voluntarily controlled. But a recent equatorial X-ray diffraction study of contracting heart muscle (Matsubara *et al.* *J. molec. Biol.* **111**, 121; 1977) has shown that a mass transfer corresponding to that in skeletal muscle occurs in this muscle too. Assuming the crossbridge movement to be radial, about 20% transfer (compared with rigor muscle) occurs during the contracting systolic phase and even during the diastolic phase there seem to be more cross-bridges near to the thin filaments (7 to 9% of the rigor transfer) than in a truly quiescent muscle. Sub-maximal tension generation was said to account for the small systolic transfer (20%)

relative to the 50 to 80% in skeletal muscle. Despite this it seems clear that comparable crossbridge movements occur in all these different muscles. But it remains to be determined what these movements really are. Are they principally radial as suggested by Huxley (see also Haselgrove *et al.* *Nature*,

261, 606; 1976) or would azimuthal crossbridge movements account more satisfactorily for the observations (Lymn & Cohen *Nature*, **258**, 770; 1975)? No doubt this fundamental problem of interpretation will be central to future equatorial X-ray diffraction studies of muscle. □

... and biochemistry

from Howard White

UNDERSTANDING the way in which muscle and other contractile systems couple the production of mechanical work to the hydrolysis of ATP will almost certainly require a detailed understanding of the mechanism of ATP hydrolysis by myosin and actomyosin (the contractile system composed of actin and myosin) and a correlation of the biochemical mechanism with the physical events of the contractile process. It is more or less accepted as dogma that during contraction the heads of the myosin molecules form cross bridges with the actin filaments, which attach and detach in a 'rowing' motion.

The mechanisms of myosin and actomyosin ATP hydrolysis (equation 1) that were outlined six years ago by Lymn and Taylor (*Biochemistry* **10**, 4617; 1971) have been especially useful because they correlated biochemistry with the cross-bridge cycle in a natural way. They showed that ATP binds to actomyosin and dissociates the myosin heads from actin before the ATP is hydrolysed. The overall rate of myosin ATP hydrolysis in the presence of actin and in contracting muscle is several hundred times more rapid than myosin alone because the reattachment of the myosin heads to actin increases the rate of the slow step of the mechanism—product release. The drive stroke in muscle presumably occurs with the return of the cross bridges to the original attached state of actomyosin without bound nucleotide.

Since Lymn and Taylor's work, the mechanism of ATP hydrolysis by myosin (or rather proteolytic fragments of myosin, S1 and HMM, which are soluble at physiological conditions and more tractable for solution chemistry) has been studied in detail. The evidence which shows that there are at least five intermediates involved in the reaction has been recently reviewed by Trentham (*Q. Rev. Biophys.* **9**, 217; 1976).

Both ATP (Step 1 and 2) and ADP (Step 6 and 7) bind to myosin in two-step reactions. The initial weakly bound

nucleotide complexes, M-ATP and M-ADP are converted at apparently identical rates to higher affinity complexes M*-ATP and M*-ADP. The transition of the high affinity complexes is associated with changes in the ultraviolet absorption and fluorescence (the number of stars given to a state gives a rough indication of the degree of enhancement of the tryptophan fluorescence). The major difference between the myosin ATP and ADP complexes is that the rate constant for M*-AXP $\rightarrow$ M-AXP is much smaller for ATP than ADP and hence ATP binds with a much higher affinity ($K_1 K_2 \approx 10^{11} \text{ M}^{-1}$), than ADP ($K_5^{-1} K_6^{-1} \approx 10^6 \text{ M}^{-1}$). The hydrolysis of ATP bound to myosin (Step 3) is rapid and surprisingly reversible, $K_3 = 10$. The rate-limiting step of myosin ATP hydrolysis is associated with the release of phosphate from the myosin thus making M**ADP-P_i the predominant steady state intermediate. The favourable free energy of hydrolysis of ATP in solution is therefore expressed primarily in the difference between the binding energies of ATP and ADP.

This type of kinetic approach is now being used to determine how actin modifies the rate and equilibrium constants of the myosin-catalysed ATP hydrolysis, and in particular to identify the rate-limiting step, and show which intermediates are common for both the myosin and actomyosin mechanisms.

Chock, Chock and Eisenberg, (*Biochemistry* **15**, 3244; 1976), and Sleep and Taylor (*Biochemistry* **15**, 5413; 1976) report that the first intermediate after dissociation of myosin-S1 from actin by ATP undergoes a fluorescence enhancement that is similar to that observed for ATP binding to myosin. Both laboratories mixed the actomyosin-S1 with a high concentration of ATP to ensure that the

change in light scattering due to dissociation of the actomyosin would be complete within the mixing times of their stopped-flow equipment and not complicate the interpretation of the fluorescence change. Although results and interpretation of the two groups differ slightly in detail, both reported that the change in tryptophan fluorescence which occurs after the dissociation of myosin from actin has a similar rate and amplitude to the fluorescence change observed for ATP binding to myosin. Sleep and Taylor were able to show by rapid quenching experiments that the ATP bound to the intermediate did not exchange with the ATP in solution (as would be expected for M-ATP). They dissociated actomyosin with stoichiometric ^{32}P -ATP and found that an excess of cold ATP added before the fluorescence increase had occurred did not reduce the amount of ^{32}P -ATP hydrolysed. It therefore seems most likely that the intermediate first released from actin is $\text{M}^*\text{-ATP}$ and that the fluorescence change occurs during the transition $\text{M}^*\text{-ATP} \rightarrow \text{M}^{**}\text{-ADP-P}_i$.

These observations are especially important, first because they link the change in optical properties of nucleotide binding to myosin with the change in optical properties of nucleotide binding to actomyosin and second, because they show that a change in fluorescence occurs at a step of the reaction that could be associated with the movement of the unattached myosin crossbridge. However, caution is necessary before suggesting that the fluorescence change is an indicator of crossbridge movement. The changes in optical properties observed for myosin and actomyosin are not unusual for the binding of large ligands to protein molecules. Furthermore, there is a conspicuous absence from the muscle literature of a demonstration that ATP induces gross physical changes in the structure of myosin, myosin filaments or myosin proteolytic fragments.

Chock, Chock and Eisenberg (*Biochemistry op. cit.*; 1976) (and for that matter Taylor and myself (*Biochemistry* 15, 5818; 1976) have found that the rate of recombination of myosin-S1-ADP-P_i with low concentration of actin, measured by turbidity, is proportional to actin concentration and equal to the steady state rate of ATP hydrolysis; this would be expected from the Lymn-Taylor model at actin concentrations where the rate limiting step is recombination of M-ADP-P_i to actin. Eisenberg also found that at rather low ionic strength and temperature ($\mu = 10 \text{ mM}$, 4°C) the steady state rate of ATP hydrolysis and recombination of S1-ADP-P_i and actin both reached a maximum of 1.0 s^{-1} at higher actin concentrations, and that the actin and

myosin remain mostly dissociated even at the highest actin concentrations. If a step associated with ADP or phosphate release were rate limiting for actomyosin AT Phydrolysis at high actin concentration, then one would expect that the predominant intermediate would be actomyosin-S1-ADP-P_i; that is, most of the myosin-S1 would be bound to actin. Because the covalent ATP bond splitting was thought to be rapid ($\sim 100 \text{ s}^{-1}$ at 20°C), they reasoned that there must be another step in the reaction, a rate-limiting transition from a myosin-S1-ADP-P_i intermediate unable to bind to actin (the 'refractory state') to an intermediate capable of interacting with actin. However, Taylor (*Biochemistry* 16, 432; 1977) has extended the original measurements of the rate of the covalent ATP bond hydrolysis and found it to be exceedingly temperature dependent. At 4°C the ATP is cleaved at only 3 s^{-1} , a value quite near the maximum rate of ATP hydrolysis, 1.0 s^{-1} , measured for actomyosin by Eisenberg at the same temperature. It is therefore possible that the rate-limiting step could be the hydrolytic step and the refractory state could be $\text{M}^*\text{-ATP}$. Moreover, it is unclear whether the rate limiting step of actomyosin ATP hydrolysis is like myosin in being associated with product release or whether it is the bond-splitting step.

One may quite reasonably wonder how

the rate and equilibrium constants determined in solution can be applied to the highly organised contractile apparatus in muscle. Taylor and I have calculated the "effective standard free energy changes" between each of the intermediates of actomyosin ATP hydrolysis using the equilibrium constants measured in solution at nearly physiological conditions and using as the standard state the concentrations of ATP, ADP, and phosphate normally present in muscle. We found that more than 50% of the "effective standard free energy change" during ATP hydrolysis is associated with the release of ADP and phosphate from actomyosin. Intuitively, it would be expected that the steps with the largest effective free energy changes in solution ought to be the ones coupled to the production of work *in vivo*. However, as has been pointed out in a very elegant theoretical analysis by Hill and Simmons (*Proc. natn. Acad. Sci. U.S.A.* 73, 36, 95; 1976) and Hill and Eisenberg (*Biochemistry* 15, 1629; 1976) restriction of actin and myosin to a given three-dimensional structure could drastically alter the distribution of the equilibrium constants between the biochemical states.

The next stage of this type of work might be to measure the rate and equilibrium constants in myofibrils or muscle fibres where the three dimensional structure and ability to do work is maintained.

New technique for surface crystallography

from John Pendry

THE detailed knowledge of atomic arrangement provided by X-ray and electron diffraction is the cornerstone of our understanding of solids. These techniques have been enormously successful and almost all commonly studied crystals, at least in the area of the physical sciences, have had their atomic coordinates determined. Recently much interest has been focused on surfaces of solids, especially on the adsorption of foreign atoms, an interest driven not only by the problems of understanding these systems, but also by the obvious relevance to more applied areas. The same basic requirements for surface atomic geometry exist as for bulk but the absence of a simple effective technique applicable to surfaces is an impediment to progress. Diffraction of X-rays cannot be used because the weak signal from a single layer of atoms on a surface would be swamped by the bulk signal, and the same is true for high energy electron diffraction. By making use of the increased

scattering cross sections of atoms for low energy electrons (0-200 eV) it is possible to do experiments sensitive to the surface and many simple surface structures have been solved in this way, but the experiments are not easy to perform. At the same time theoretical interpretation is involved, limiting accuracy to the $0.1 \text{ \AA}$ level, and effectively blocks extension of the method to complex surface structures. The search is still on for the definitive surface crystallographic technique.

In recent experiments performed on the Stanford synchrotron radiation project (reported by P. H. Citrin at the March 1977 meeting of the American Physical Society in San Diego; see also Stern *et al.* *Phys. Rev. Lett.* 38, 767; 1977), a revolutionary way of solving surface structures has been demonstrated. In one recent experiment the adsorption of iodine atoms on to a face of a single crystal of silver was studied. X-rays were used but not in a diffracting mode: instead their energy was tuned close to one of the inner-electron energies of an iodine atom. The ejected electron behaves like a radar pulse originating from the excited atom. Surrounding atoms can scatter the out-

John Pendry is Head of the Theoretical Physics Group at the Daresbury Laboratory.

going electron back to the source where the scattered electron wave interferes with the outgoing wave, modulating the probability of electron emission relative to the free atom value. Figure 1 shows a sketch of the process. The following formula describes the modulation to a good approximation:

$$\chi(k) = \frac{I(\text{surface})}{I(\text{free atom})} = \sum_j f_j \frac{\sin(2kR_j + \psi_j + 2\delta)}{kR_j^2}$$

where

$$\frac{\hbar^2 k^2}{2m_e} = \hbar\omega - E_c$$

E_c is the binding energy of the core level, $\hbar\omega$ is the photon energy, R_j the distance to the j th neighbour, f_j and ψ_j the amplitude and phase of scattering by the j th neighbour, and 2δ a shift in phase of the wave, caused by refraction in the potential of the emitting atom. The structure is commonly referred to as EXAFS, standing for extended X-ray absorption fine structure, but it must be stressed that the structure is in fact generated by the diffraction of electrons produced by X rays within the surface. χ can be measured for a whole range of k values by increasing the energy of the input photon, so that χ can be Fourier transformed to pick out the various sine-wave components and hence to find R_j . Some corrections must be applied for the k -dependence of f_j , ψ_j and δ , but these can be calculated quite accurately from theory.

The question remains of how to measure $\chi(k)$. X rays of variable energy can be obtained by monochromating a continuum source. High power X-ray tubes have been used, but by far the best source is a synchrotron or storage ring

which emits very powerfully in the X-ray region. The innermost shell, the K shell, is usually chosen for the experiment and cross sections are sufficiently large for a substantial number of surface atoms to be excited. The probability of electron emission can then be monitored in one of several ways. When the technique is applied to bulk atoms the electron emission probability can most simply be monitored by the absorption coefficient for X rays, but for a surface experiment this method is not sufficiently sensitive. Alternatively the presence of excited atoms can be detected by their eventual decay by way of an Auger process involving emission of a second electron of fixed energy independent of the first electron's emission energy. Sensitive electron detectors are available and the Auger signals can easily be detected. It was in this way that χ was measured for the iodine on silver investigation.

The experiments have shown that it is possible to use the EXAFS technique at surfaces and have confirmed an earlier determination of the structure by electron diffraction. Interpretation of these experiments is sufficiently simple and well understood that ultimately an accuracy of 0.01 Å should be obtainable, an order of magnitude better than previously possible, and in addition extension to more complex structures is feasible. There are limitations to the technique. Only signals from surface atoms of a type different from those in the bulk can be examined. Not all atoms have inner levels suitable for the experiment because the current generation of X-ray monochromators cuts off at long wavelengths leaving the light elements such as oxygen and carbon inaccessible for the moment. Even if an inner shell can be excited, a suitable Auger transition for the monitoring process must be found. Despite these limitations surface EXAFS is the most striking advance in surface crystallography in recent years. □

appears to be due, says Liane Reif-Lehrer of Harvard Medical School, to monosodium glutamate, which is also used in Japanese, Italian and French restaurants. All-American establishments seem to be blameless.

Reif-Lehrer brought the full resources of modern investigative techniques to bear on the problem, and the encoded results were analysed on a computer at the Eye Research Institute of the Retina Foundation. Over 2,000 individuals of all ages were interrogated, including groups of grade-school children in the towns of Needham and Wellesley, Massachusetts; "the socioeconomic situation of these towns was such that these children were likely to have had multiple exposure to Chinese restaurant food". In addition, public notices were issued encouraging sufferers to describe their experiences. To test whether those who exhibited symptoms were more likely to reply to the questionnaire than those who had never suffered, and who therefore put it in the wastebasket, the non-responders were further pursued by post and by telephone; nevertheless an obstinate 3 still refused to answer the questions. A further 22 "did not answer telephone or had terminated appointment". How many of these had suffered nervous breakdowns on account of all the pestering is not recorded.

Among those who gladly volunteered to describe their symptoms, the majority of those susceptible to CRS (about 25% of the total) reported combinations of such commonplace but disagreeable symptoms as headaches and vomiting, diarrhoea and dizziness, sneezing and stomach cramps; not to mention tightness around the face and burning in the upper torso. It is, however, in the list of 36 "other symptoms" that the full horrors of CRS emerge. Depression, hallucinations and an urge to laugh and cry were reported; also excessive perspiration, a feeling of having heavy arms and legs, or "head feels unattached". Less alarm-

Fig. 1 Electrons emitted by an activated atom are bounced back off neighbouring atoms with a phase lag determined by the interatomic distance and the electron energy.

Advances in Chinese Restaurant research

from a Correspondent

INVESTIGATION of the dreaded Chinese Restaurant Syndrome (CRS) continues to grip the Boston medical research community like a fever. Another comprehensive account of the range of symptoms induced in some of those who (despite it all) still eat Chinese food has just appeared in *Federation Proceedings* (36, 1617; 1977). The list bears comparison with any mediaeval catalogue of bodily ailments. It all

ing were feelings of drowsiness or a "sense of fullness after limited amount of food". Four respondents blamed their Chinese meal for insomnia, while one said it made him feel "high". Another complained of loss of reflexes, making it hard to carry out typing. Others felt paralysed in the neck or backbone, and one unfortunate had a "mental image of a buzzing sound". There was also a wide range of ocular disturbances, from blurred vision to scintillating scotoma (the research was supported by a grant from the National Eye Institute). The most dramatic description, sparing no detail, was "Burst blood vessel and occasional sensation as if pins were being stuck in the eyeball".

All these fascinating data were analysed exhaustively with respect to the respondents' age and sex, though 337 people unaccountably failed to disclose the latter. It seemed that the 26-30 age group was the most at risk. Replies from the 317 children tested were dis-

missed for some reason as "far less reliable than the adult data", but their descriptions have nevertheless the ring of truth; many of those afflicted reported their only reaction as being a stomach ache, while some felt "fat", "stuffed", or "very full" after a Chinese meal. Two children did say that they "felt very funny" and others reported milder reactions, but none described such an interesting variety of bizarre symptoms as their elders, most of whom were faculty members or college students. Perhaps the children's vocabularies were insufficiently developed.

The author ends with thanks to a veritable army of helpers, including five who "stuffed envelopes". Her appetite for symptoms seems only whetted by this wide-ranging exercise, and she says "we hope to provide more definitive data on this matter in the near future". The First International CRS Symposium can hardly be far away. □

Rat readings

If to have a newsletter devoted to one confers the ultimate cachet of respectability in the animal world, the laboratory rat has been unaccountably neglected. A new periodical 'Rat News Letter', published by the UK Medical Research Council's Laboratory Animal Centre now puts the rat on a par with several of its laboratory companions. The purpose of the newsletter, which is intended to appear twice a year, is to serve as a medium for the informal exchange of information on all aspects of the biology of the laboratory rat, but with special emphasis on the use of genetically defined rats in biomedical research.

The first issue announces the discovery of an athymic nude mutation which occurred spontaneously in the hooded rat colony at the Rowett Research Institute. This mutant is being bred at the Laboratory Animal Centre and will probably begin to become available in small numbers by the end of the year.

The vexed question of nomenclature for the alloantigenic loci is discussed and the issue also contains contributions from research establishments throughout the world giving details of their interests, and holding of strains, stocks and mutants. The editor is Dr Michael Festing, MRC Laboratory Animal Centre, Woodmansterne Road, Carshalton, Surrey SM5 4EF to whom contributions for publication and enquiries about subscriptions (£5.00/\$10.00 for four issues) should be sent.

Phobos and Deimos, the moons of Mars

from David W. Hughes

A discussion meeting to review our present knowledge of the Martian satellites was held by the Royal Astronomical Society in London on 13 May, 1977, under the chairmanship of Dr G. E. Hunt of the Meteorological Office.

AUGUST 12, 1977 is the hundredth anniversary of the discovery of Phobos and Deimos and meetings are being held in London and Washington to commemorate this event. The discovery was made by Asaph Hall, an astronomer at the US Naval Observatory, Washington DC, using their new 26-inch refractor at the old observatory down by the Potomac river. In 1877 this was one of the best telescopes in the world. Hall started his search in early August, his first few nights being unsuccessful. Discouraged, he was all for giving up but his wife (*née* Angeline Stickney) urged him to spend a few more nights at the telescope and on the 12th he discovered Deimos. While confirming this observation Hall discovered Phobos on the 17 August, the two new satellites being announced on 19 August. Hall named them Phobos (fear) and Deimos (terror or panic) after the horses that pulled the chariot of the god of war in Greek

mythology. Interestingly the two Martian moons had been discussed in the literature before their discovery. Johannes Kepler (1571-1630), a great lover of mathematical progressions, had decided that as Earth had one satellite and Jupiter four (only the Galilean satellites were known at that time) then Mars, the planet in between, should have two. Voltaire and Swift mentioned them in *Micromegas* and *Gulliver's Travels*, Swift in 1726 going so far as to predict the correct values for their orbital revolution periods.

Hall observed Mars during a very favourable opposition when the distance between Earth and Mars was at a minimum (~ 0.57 a.u.). At their greatest elongation from Mars the two satellites are only 22 and 56 arc s from the centre. Even here it is extremely difficult to pick them out from the halo of scattered light that surrounds the telescopic image of Mars. The fact that they are about 3×10^3 times fainter than Mars does not help much either.

At the London meeting D. Pascu (US Naval Observatory) discussed Earth-based observations of the satellites with special reference to the accidental and systematic errors inherent in positional observations. Before 1941 visual measurements were made of the distance between the satellites and of the angle the two subtended at the centre of the planetary disk. The rapid motion of the satellites and the problem of estimating the disk centre, added to

problems of visual astigmatism, made these measurements very difficult. Photography has been used since 1941, small circular or lozenge shaped nicrome filters deposited on optically flat glass plates being used to equate the brightness of the planet and satellite. This technique obviously reduces the personal error and with exposure times mainly between 10 and 20 s the satellites do not move very far during the exposure time. Photography thus reduces the positional error from about 0.6 arc s to less than 0.1 arc s.

Photometric observations are greatly hampered by the logarithmic intensity gradient of the planetary halo and only integrated results over the whole satellite disk are possible and these only to ± 0.1 magnitudes. Pascu concluded by saying that spacecraft pro-

David W. Hughes is a lecturer in the Department of Physics at the University of Sheffield.

vided positional results comparable to the best Earth based astrometric observations. The sparsity of the spacecraft data is ample justification for the continuance of telescopic observation.

Orbits

G. A. Wilkins (Royal Greenwich Observatory) discussed the orbits of Phobos and Deimos making special reference to the way in which these are varying with time. Deimos orbits Mars in 30 h 18 min and Phobos in 7 h 39 min, Phobos having the strange distinction of being the only satellite in the Solar System which orbits its central body faster than that body spins on its axis. Looking at the satellites from the surface of Mars Deimos would rise in the East and set in the West just like our Moon does but Phobos rises in the West and sets in the East. There are two other strange things about the orbit of Phobos. First its mean distance from the centre of Mars is 9,400 km whereas the Roche limit is about 8,700 km (any fluid body getting closer to Mars than 8,700 km will be pulled apart by differential tidal forces). Second, it is getting closer. This automatically increases its mean orbital velocity V , Sharpless (*Astr. J.* **51**, 185; 1942) concluding that $\Delta V/V$ per period was about 8×10^{-12} . This secular acceleration could be caused by a resisting medium in the region of the satellite orbit (the outer remnants of a Martian atmosphere?) or be a consequence of tidal friction, the absence of seas on Mars however requiring this to be a body tide. The Soviet astrophysicist Shklovskii in the 1950s favoured the former explanation postulating that the large $\Delta V/V$ was due to the low density of Phobos; he suggested a density of $10^{-3} \text{ g cm}^{-3}$. Shklovskii astounded the scientific world by suggesting that Phobos was in fact a hollow, artificial satellite produced by an advanced Martian civilisation.

Wilkins was not convinced that present-day analysis of observational data indicated that there was any secular acceleration taking place. Spacecraft data seemed to indicate that it was at least a factor of three smaller than that deduced by Sharpless. Even at this lower rate Phobos would crash on to Mars in about 10^8 years assuming of course that it was not pulled apart into a myriad of rocky pieces on coming closer than the Roche limit. Such a disruption would give Mars a ring system like Saturn and Uranus.

Spacecraft observations of the surface features of the Martian satellites were discussed by Jo Veverka (Cornell University) (see also *Scient. Amer.*, February 1977). In 1971 Mariner 9 obtained 29 views of Phobos and 9 of Deimos with an average resolution of 200 m. Surprisingly both satellites were

found to have almost identical shapes, that of triaxial ellipsoids, Phobos having principal diameters of 27, 21 and 19 km, Deimos of 15, 12 and 11 km. Why this is so is still somewhat of a mystery. However, Don Gault (Ames Research Centre) found that high velocity impacts on spherical targets produced a crater at the impact point, spalling on the opposite side of the sphere and often the complete removal of the entire outer layer of the target. The inner core left behind had a shape surprisingly like that of Phobos and Deimos. Both moons rotate synchronously with their orbital periods and their long axes pointing directly at Mars.

View from Viking

The moons are not the same colour as Mars. Mars is red, they are blackish-grey, indicating that the surfaces have different compositions. Albedo and spectral reflectance measurements indicate that the satellite surfaces are made of C1 carbonaceous chondritic material similar to the Orgueil meteorite and the asteroid Ceres. This material has a density of about 2.0 g cm^{-3} . Crater counts indicate that the surfaces are at least 2×10^9 yr old and Veverka concluded that the satellites must have been formed in the asteroid belt and have moved to Mars later on. The Viking spacecraft has approached as close as 100 km to the satellite surface and has obtained pictures with a resolution of about 10 m. These pictures reveal curious rill-like fracture patterns around Stickney, a 10 km diameter crater on Phobos. (This crater has a diameter about 40% the maximum diameter of Phobos itself!) These could be failure cracks produced in the rocky satellite when the crater was formed. Crater chains have also been found, these being parallel to the orbital plain (which is also the equatorial plain of the satellite). These could be formed by secondaries blown off the satellite by impact events, these secondaries having velocities lower than the escape velocity from the Martian gravitational field. After orbiting the planet for a time (that can be as long as 50 yr) some of these fall back on to the satellites, forming secondary craters. The surface also contains peculiar groove-like striations, these forming segments of a series of small circles which are all perpendicular to the Mars-satellite line. Tidal mechanisms are being considered as a possible source of these.

W. Michael (Langley Research Centre) discussed the changes induced in the orbit of the Viking space probe by its close approach to Phobos. These indicate that Phobos has a mass of $1.1 \times 10^{19} \text{ g}$ (about 2×10^{-8} the mass of Mars). The uncertainty in this value is

about $\pm 15\%$ and coupled with a volume which is also known to $\pm 15\%$ this gives a density with a probable value between 2.1 and 2.2 g cm^{-3} and an error of about $\pm 20\%$.

The problem of the origin of the Martian satellites was discussed by M. Woolfson (York University). Theories are legion—a usual case when there is not enough available evidence. Most have the two satellites originating at the same time mainly because their orbital orientations are similar, as are their photometric characteristics. They are thought of as being planetismals left over from planetary formation, condensed filaments produced by collapsing protoplanets, captured asteroids that crawled into the inner Lagrangian points then lost energy by tidal friction giving them more stable orbits, fragments from a disrupted asteroid that passed within Mars' Roche limit, fragments from a collision between two asteroids that took place within Mars' gravitational sphere of influence or fragments produced by collisions between protoplanets or between protoplanets and Jupiter, these collisions resulting in all the asteroids and terrestrial planets and their satellites.

So a hundred years has seen a vast increase in our knowledge of these two fascinating satellites. One of the bonuses of sending a spacecraft to Mars is that you have these asteroid-like bodies on hand for investigation if Mars becomes blotted out by dust storms. Viking went within 100 km, let us hope that in the near future a spacecraft will be sent to land on Phobos or Deimos to see what their surfaces are really like. □

A hundred years ago

THE annual meeting of the Institution of Mechanical Engineers opened on Tuesday at Bristol. Mr. T. Hawksley, C.E., in his opening address, said it was the duty of the government to adopt such timely measures as would secure to us the paths of the ocean for our food inwards and our manufactures outwards. He deprecated the building of enormous and unwieldy floating castles, and advocated the construction of a fleet of swift, light, well-engined ships, equally capable of sailing or steaming. He thought the extreme action of some of the working classes the cause of England's trades going abroad.

From *Nature* **16**, 26 July, 256; 1877.

Prospects in oceanography

At a time when science in general has lost its magic, the science of the earth—and especially of its mysterious ocean—has been increasingly appreciated for its combination of difficulty and importance.

Plate tectonics helped a lot by providing a unifying hypothesis which could be readily grasped, and which justified the investment in earlier observations at sea, especially of the magnetic field. The deep drilling programme, now IPOD, has been a triumph of science, technology and organisation. The physical oceanographers have learned how to make direct measurements of ocean currents and discovered that the deep ocean is quite different from what they expected. There are eddies which may well be the marine equivalent of atmospheric depressions, longer lasting but smaller and slower. If they resemble atmospheric depressions to the extent of dominating the poleward transfer of heat they will be vital to our understanding of climate and climatic change. Marine biologists can now unambiguously sample macro-plankton in the deep ocean; zoogeography is becoming a quantitative science at last. Marine chemistry is now a subject in its own right.

Much of this progress has been made possible by instrumental development and skilled engineering. We have exchanged our sextants for satellites, we can dive into rift valleys, we can image the earth from space and make micro-photographs at fantastic magnification. And yet we have only just started to understand the ocean; it remains dark, mysterious, enigmatic, the last great pit of ignorance on our planet. There are simple-sounding questions to which we cannot yet give satisfactory answers. An engineer designing an offshore structure may feel that we should know how surface waves are generated by the wind. A forward-looking fisherman might expect us to know about the life-cycle of krill. A climatologist might think that we should know how much heat the Gulf Stream transports.

Oceanographers used to form a small group of rather eccentric, half-scientist, half-seaman explorers. Everybody knew that the ocean provided a support for ships, a source a food, a sink for waste and a regulator of climate, but it wasn't thought that science could help the engineers much. In those days, not so long ago, anyone making a long series of wave-observations would have been accused of wasting taxpayers' money. Now he is asked why he hadn't made many more.

There is an inevitable mismatch between the timescale of marine research and of the practical problems to which it can contribute. Environmental problems arise unexpectedly; stamping them 'immediate' cannot reduce the time it takes to make the necessary observations or get some fundamental understanding. Oceanographers must, therefore, gather as much basic information as they can: they cannot predict, any more than anybody else, what problems will come up so they must necessarily work on a variety of problems, trying to connect them into a self-supporting generality from which special cases can be sensibly studied.

The money spent on such basic research is perhaps analogous to a life assurance premium to guard against an inevitable contingency rather than to react to a particular, predictable event. It is generally desirable to pay one's assurance premium regularly and over a long period. Marine research is a bit too long-term to suit most of its customers, to use the present jargon. Perhaps it needs patrons rather than customers; in the long run, as Lord Rothschild probably appreciates, it is selective patrons who get rich.

A few problems are, however, so long-term as to be foreseeable. One concerns the disposal of high-level radioactive waste. It might be placed on, or preferably in, the sea floor; a study of the effects is clearly essential. Fortunately much relevant information and expertise is already available, thanks to an investment in basic research, so progress can be made fairly quickly, which in this context means in a decade or two.

Another long-term problem is climatic change. Man is vulnerable to relatively small changes in his environment; there is growing concern that we know so little about the mechanism of climatic change, that we cannot assess whether, or to what extent, man's activity contributes to it. If anything is clear it is that the ocean is an important component in the system—the pioneers of air-sea interaction and of ocean circulation studies weren't frittering away the taxpayers' money after all. There is a lot left to do—and it will take a long time.

Long-term, the outlook for oceanography seems good. The short-term gloom stems from a basic incompatibility between an indivisible ocean and an increasingly nationalistic world, which is offsetting what some find the main attraction, the combination of personal effort with international cooperation. Sensible legislation is clearly desirable and able scientists and lawyers are working on it. But it does not seem likely that United Nations Conferences on the Law of the Sea can do much to create the goodwill needed, whatever is finally agreed. The badly needed bridge between politics and science can only be filled by the slow process of education. It may well be that training and mutual assistance in marine science is the most valuable contribution some mature oceanographers can now make. There is a growing risk that marine research will be slowed down, not so much by lack of access but because the bright young people on whom progress depends will prefer a branch of science where freedom to make observations does not depend on unpredictable and unexplained bureaucratic decisions.

Some may argue that a check to the progress of marine research would be a justified casualty of peace, a transient on the way to a new world order. It seems much more likely that oceanographers will be in the lead.

Henry Charnock

Professor Charnock is Director of the Institute of Oceanographic Sciences, Wormley, Surrey, UK.

Developments in the Law of the Sea

Edward Miles

Institute for Marine Studies HA-35, University of Washington Seattle, Washington 98105

In this and the following article developments in the law of the sea are described and their impact on marine research is considered. Agreement seems close on much of the negotiating text concerned with coastal and economic zones. But beyond, on the sea-bed in deep water, there are still many difficulties to be resolved. Is the outlook for scientific research therefore bleak? It is argued that if scientists come to terms with the new order, prospects for research in the economic zone and beyond could well be bright.

United Nations Conferences on the Law of the Sea and Associated Meetings

First UN Conference on the Law of the Sea (UNCLOS), Geneva, 25 February–27 April 1958.

Second UN Conference on the Law of the Sea, Geneva, 17 March–26 April 1960.

Ad hoc Committee to Study the Peaceful Uses of the Sea-bed and the Ocean Floor beyond the Limits of National Jurisdiction. (Established by UN General Assembly resolution 2340 (XXII) of 18 December 1967.) Three sessions, New York and Rio de Janeiro, March–August 1968.

Committee on the Peaceful Uses of the Sea-bed and the Ocean Floor beyond the Limits of National Jurisdiction. (Established by UN General Assembly resolution 2467 (XXIII) of 21 December 1968.) Eleven sessions (plus additional meetings), New York and Geneva, February 1969–August 1973.

Third UN Conference on the Law of the Sea. (Established by UN General Assembly resolutions 3029A (XXVII) of 18 December 1972 and 3067 (XXVIII) of 16 November 1973). First session (administrative matters only), New York, 3–15 December 1973; Second session, Caracas, 20 June–29 August 1974; Third session, Geneva, 17 March–10 May 1975; Fourth session, New York, 15 March–7 May 1976; Fifth session, New York, 2 August–17 September 1976; Sixth session (scheduled), New York, 23 May–8 (or 15) July 1977.

IN the latter half of the twentieth century the strategic significance of the ocean has substantially increased as a result of the relative invulnerability of the submarine-based deterrent. At the same time, the incidence of violent conflict over purely ocean-related issues has been quite low. But, since the first attempts to codify the Law of the Sea under the auspices of the League of Nations in 1930, there has been a dramatic increase in non-violent conflict over ocean resources, both living and non-living.

The most contentious issue of the period 1920–60 was the limit of the territorial sea as it pertained to jurisdiction over coastal fisheries. This, in turn, was linked to the issue

of freedom of passage through straits used for international navigation since such passage was seen to be threatened by the extension of coastal state jurisdiction over fisheries. In 1968–69, the major problem in the UN Sea-bed Committee was the question of limits to the continental shelf and jurisdiction over the ocean floor beyond the shelf. In 1973–77 at the Third United Nations Conference on the Law of the Sea (UNCLOS III), the shelf and sea-bed remain contentious issues but the number of controversial problems has proliferated. These include the exclusive economic zone concept, straits used for international navigation, archipelagos, islands, scientific research, ship-generated pollution and a host of other things.

The primary function of the law of the sea has always been to arrive at some balance between the exclusive interests of a few states relative to any particular use of the ocean in various spatial locations and the inclusive interests of the rest of the world system. Since 1930 the search for a globally acceptable balance has been posed increasingly in terms of choosing between the inclusive interests of free navigation and the exclusive interests of extending coastal state control over living and non-living resources in wider areas of the water column and continental margin adjacent to their coasts. It is estimated that the focal point of the current negotiations, the 200-mile exclusive economic zone, would result in an additional 35%–37% of the landmass of the planet passing under national control.

The conferences of 1958 and 1960 differed from that of 1930 in the number and type of participants. Twice as many countries (86 and 88) participated in the latter as in the former (44). Expectations about the possible contributions of marine technology and ocean resources to national development seem to have been significantly stimulated at this time. In 1974 participation in UNCLOS III became almost universal with 137 participating countries, out of the 149 invited. In 1976, the number of participants increased to 156. The alignments in the UN Sea-bed Committee from 1968–73 and in UNCLOS III itself were no longer those of the General Assembly but resembled the alignments of the United Nations Conference on Trade and Development (UNCTAD) more and more. In doing so they foreshadowed Assembly politics of the 1970s with the emphasis on the confrontation between advanced industrial and developing countries. This was clearly the most complicated, and perhaps the most difficult, law-making conference the United Nations had ever hosted. There were many more countries represented than ever before; consequently many more interests had to be reconciled. Many of these interests seemed mutually exclusive. Given the primacy of the North–South confrontation, no single group seemed capable of providing effective global leadership.

Technical experts, though in attendance, were tightly controlled by their delegations. They were not allowed to have any independent role as in 1958, since science itself had come under heavy attack. There was no longer any trust and repeated assertions about the necessity of facilitating disinterested scientific investigations of the world ocean

were consistently denied. This was a fight to redistribute ownership and control over world ocean resources and science was seen to be a weapon in this fight.

States differ both in the variety of ocean-related capabilities they command and in the marine biogeophysical conditions which they face. These differences are of particular importance in explaining much of the political behaviour and outcomes in the negotiations. But, in addition, the process and the results of negotiating are very significantly affected by the dynamics of conference diplomacy in global settings. These dynamics include the need to build and maintain 'winning' coalitions as defined by the majorities in the Rules of Procedure, the method of arriving at decisions, the extent to which purely ocean-related issues are affected by considerations external to the oceans, and many other factors.

Emergence of a new regime for the oceans: content and process

Content: The heart of the new regime is contained in two documents: the Revised Single Negotiating Text (RSNT), Parts II and III. Although a few issues remain to be resolved, the outlines of the new law of the sea are in fact quite clear. The situation relating to the sea-bed beyond national jurisdiction, however, presents grave negotiating difficulties and threatens the whole conference with official failure, that is, no treaty. Consequently, the RSNT, Part I, is at the moment extremely controversial.

The basic ingredients of the package in the RSNT, II and III, are as follows. (1) A 12-mile territorial sea with separate regimes governing innocent passage and passage through straits used for international navigation. (2) An exclusive economic zone of 188 miles beyond the outer limit of the territorial sea wherein the coastal state exercises sovereignty over living and non-living resources, exclusive jurisdiction with respect to other activities like scientific research, and jurisdiction with respect to yet other activities like preservation of the marine environment. (3) The coastal state exercises sovereign rights over its continental shelf, which is defined as either the continental margin (including the shelf, the slope and the rise) or 200 miles, whichever is greater. (4) Archipelagic states may draw straight baselines connecting the outermost points of the outermost islands and drying reefs, before delineating the outer limits of the territorial sea, economic zone, and continental shelf. (5) Island states may extend jurisdiction as described but "Rocks which cannot sustain human habitation or economic life of their own shall have no exclusive economic zone or continental shelf" (Article 128, paragraph 3).

The RSNT, III, is itself divided into three parts. The first part deals with preservation of the marine environment and contains primarily very general obligations for states relating to pollution from land-based sources, from or through the atmosphere, and by dumping. The most controversial section (VII) is contained in Articles 23-42 dealing with the enforcement of these provisions over ships and particularly over vessels operating within the economic zones of coastal states. The source of controversy is that the issue is linked to the status of the economic zone as it affects navigation and therefore the security interests of particular maritime states. In a similar fashion, the part on marine scientific research also has broader implications but the specificity of coastal state control is greater. There are, however, some incompatibilities between the approaches adopted in Parts II and III.

With respect to the sea-bed issue, the major points of controversy are as follows. (1) The basic principle governing

exploitation of the area and its resources. The Group of 77 insists that there be only two modalities: either the International Authority directly and exclusively exploits the resources and/or the Authority exploits in conjunction with other contracting parties via the mechanism of joint ventures. On the other hand, the advanced industrial countries insist that a third modality be allowed, that is, exploitation by contracting parties alone. (2) The detailed rules and regulations governing the relationships between the Authority and contracting parties. (3) The structure, functions and powers of the International Sea-bed Authority and, in particular, the method of making decisions within the Council. (4) The method of financing the Enterprise which is to be the operating arm of the Authority. And (5), the question whether the Authority is to be given the competence to set its own resource policy; this implies the capacity to impose production and price controls on contracting parties.

Process: From the first substantive session in 1974, the Conference has suffered from the problems of size and complexity incurred in attempting to negotiate an agenda of more than 100 issues simultaneously among 137-156 nation-states. These difficulties have been aggravated by the Rules of Procedure which emphasise the necessity of achieving consensus, the dynamics of global conference diplomacy which are often at odds with the distribution of interests in the substantive problems being negotiated, and the considerable natural inertia which such a social system brings in its train.

Even during the preparatory phase (1971-73), it was clear that there would be two major overlapping dimensions to the conflicts which would arise in the Conference. The first, already mentioned, would pit developing countries against advanced industrial countries. The second, however, would cut across the former by pitting all landlocked and geographically-disadvantaged countries against those coastal states which stood to gain most from the exclusive economic zone concept. The combined effect of these two factors was to increase the probability that no coalition would actually have the votes to achieve a two-thirds majority and therefore significantly to delay the emergence of a treaty.

The second major problem of the negotiation process at UNCLOS III concerns the sea-bed issue in Committee I. This was in reality a four-dimensional problem. The first dimension was that only 20-30 countries actually had substantive interests at stake in the negotiations. For the remaining 100 or so delegations the symbolic issues were paramount and this was the issue on which the North-South confrontation was at its most extreme. The second dimension is represented by a group of states, led by Algeria, seeking to make this issue into a central issue of the New International Economic Order. They were ultimately successful in this strategy and were significantly aided in doing so by the third dimension: a very serious internal split within the US delegation between the Departments of the Treasury and Interior over the line that would be followed. The fourth dimension was an idiosyncratic one but very significant, nonetheless, since it involved a severe personality conflict between the chairman of Committee I and the chairman of Committee I's Working Group. All of these dimensions affected the negotiations in important ways which we do not have the space to describe in detail.

One final point should be made about the process of negotiations in Committee I. As a result of the scope and technical complexity of the issues being dealt with, each major issue was negotiated separately rather than in a total package as in Committee II with the economic zone and transit through straits. Consequently, the same confrontations occurred at every stage and increased the difficulties of reaching agreement.

Probable outcomes and their effects

Will the Conference be able to produce a treaty or not? This depends primarily on whether either the advanced industrial countries or the Group of 77 capitulate on the major issues of access to and control of the international sea-bed area. If the United States capitulates, it is not clear at the moment that either the EEC countries, Japan, or the US Senate will concur. If there is continued stalemate, the Conference will be by-passed by unilateral action of the US Congress probably in late 1977 or early 1978. In that event, undoubtedly the EEC countries and Japan will follow suit.

While the sea-bed is the primary problem for the next session (May–July 1977), there are still three difficult issues remaining in Committees II and III. (1) The status of the economic zone or whether the zone is to be declared waters under national jurisdiction with specified easements for coastal states or vice-versa. If neither is the case, the problem is whether the zone is unique. The underlying problem concerns the residual rights of navigation within the zone and their significance for the defence establishments of the USA and USSR. (2) The problem of coastal state control of scientific research undertaken within its economic zone. (3) The continued, intense opposition of the Group of landlocked and 'geographically-disadvantaged' States to the articles establishing the economic zone. While

these are difficult problems, there are indications that solutions can be found.

If the Conference breaks down over the sea-bed issue, the result is likely to be continued controversy over the RSNT, I, but a high degree of acceptance of the provisions contained in the RSNT, II and III. Re-revised versions of these are likely to be presented as formalised President's Texts outlining the new regime for the oceans. Already, in the large number of unilateral extensions of coastal state jurisdiction of 200 miles, most of them are obviously patterned after the RSNT, II.

What then are the likely substantive effects of such a regime? The most sweeping changes would relate to fisheries wherein almost all the world's demersal species currently fished and about 60% of tuna and tuna-like species will pass under national control. The effects on management of tuna in the short term will be grave since control over the stocks will be fragmented. The stability of the regime for navigation will be in question as far as the issue of coastal state control over ship-generated pollution in the economic zone is concerned. The scientific research activities of advanced maritime countries, and particularly of the USA and USSR, in the economic zones of other coastal states are likely to be adversely affected. Finally, it will become increasingly more clear that the economic zone will be a multi-purpose zone for which a capacity to provide co-ordinated management across all activities should be developed.

Implications of the Third United Nations Conference on the Law of the Sea for marine scientific research

Desmond P. D. Scott

Intergovernmental Oceanographic Commission, Unesco, 7 Place de Fontenoy, 75700 Paris, France

THE Third United Nations Conference on the Law of the Sea (UNCLOS) and its predecessor—the United Nations Committee on the Peaceful Uses of the Sea-bed and the Ocean Floor beyond the Limits of National Jurisdiction—have, for the last 10 years or so, from a starting point of Arvid Pardo's 'Common Heritage of all Mankind', been steadily trying to reach agreement as to how the resources of the oceans beyond the limits of the old territorial sea—a cannon shot range of 3 miles from the coast—can be divided equitably between the 150 odd sovereign member states of the United Nations.

Numerous other problems have arisen along the way which have required investigation and solution but the resources, both living and non-living (mainly the latter), are the sole real reason for the whole exercise.

This monumental task which is as yet far from complete, seems to be moving at a desperately slow pace but it should be remembered that it is indisputably the greatest single attempt ever made to develop an entirely new international legal regime for a highly complex subject area having numerous facets and linked interests, all of which have to be taken into account. When complete the resulting Convention will cover the waters of the oceans, the sea-bed and the subsoil beneath, over an area covering more than 70% of the surface of the globe. It should be realised that the First UN Conference on the Law of the Sea (the Second

was limited in scope and was a failure) was, in essence, an attempt to codify existing traditional laws that had developed haphazard over the years, but that this is an entirely different type of exercise that cannot be carried out in a hurry if the final result is going to be acceptable to a majority of the countries of the world.

It has been said that the Conference is an attempt to avoid the development of a situation similar to the African land grab of the nineteenth century but in the event, this is exactly what has occurred but with more contenders for the prize and no indigenous peoples to cause difficulties in later years.

The preceding article describes the way in which the Law of the Sea has developed, so no attempt has been made herein to identify the various draft articles and discussions dealing with marine scientific research. But, there are a number of basic agreements that have now been reached and are certain to become generally accepted law in the next few years whether or not an acceptable Convention is forthcoming from the Conference; the likely effect of these on the future of the marine sciences is considered below.

Crisis in marine research

It cannot be denied that fundamental marine scientific research and much applied research of vital importance to developing as well as developed countries, is now facing a

REMOTE SENSING OF ENVIRONMENT

Edited by
Joseph Lintz, Jr., Mackay School of Mines
University of Nevada
David S. Simonett, Department of Geogra-
phy, University of California, Santa Barbara

"Remote Sensing of Environment" is a timely volume appearing at the height of world interest in ecology, resource, and energy management. Twenty experts discuss the many aspects of remote sensing: fundamental principles, instrumentation, processing and technique, and applications of airborne and spaceborne systems for the development and management of the earth's natural resources. The text is multidisciplinary and essentially non-mathematical.

Part I REMOTE SENSING PRINCIPLES AND CONCEPTS
Contributors: R J Curran, J Everett,
R S Fraser, R J Pogorzelski, K A Shapiro,
D S Simonett

Part II INSTRUMENTATION FOR REMOTE SENSING
Contributors: A Barringer, R N Colwell,
F J Janza, J Lintz, D S Lowe, R K Moore,
D S Simonett

Part III REMOTE SENSING SUPPORTING FUNCTIONS: DATA PROCESSING, GROUND TRUTH, AND MISSION PLANNING
Contributors: P A Brennan, P E Chapman,
E J Hajic, D A Landgrebe, J Lintz,
D S Simonett

Part IV REMOTE SENSING APPLICATIONS: ANALYSIS, INTERPRETATION, AND RESOURCE MANAGEMENT
Contributors: R W Peplis, F F Sabins,
D S Simonett, H E Skibitzke, D Walsh

Author and subject indexes, more than 900 references
color illustrations
1976, xx, 694 pp

COMMUNICATION SYSTEM PRINCIPLES

Peyton Z. Peebles, Jr.

The University of Tennessee

A much-needed text on principles and systems of communication theory for graduates and advanced undergraduates of varying backgrounds, this book will be of interest also to practicing engineers and researchers in electrical engineering. More than twenty comprehensively presented systems are considered. Problems and references are included at the end of each chapter.

Contents: Introduction. Deterministic Signal Representations. Deterministic Signal Transfer through Networks. Statistical Concepts and the Description of Random Signals and Noise. Amplitude Modulation. Angle Modulation. Pulse and Digital Modulation. Carrier Modulation by Digital Signals. System Power Transfer and Sensitivity Problems. References. Appendixes. Index.

1976, xix, 488 pp, illus
Hardbound ISBN 0-201-05758-1 \$22.50
Solutions Manual
for Instructors ISBN 0-201-05759-X \$3.50

QUALITATIVE METHODS IN QUANTUM THEORY

A. B. Migdal, I V Kurchatov Atomic Energy
Institute and Akademia Nauk, Moscow, U.S.S.R.
Translated from the Russian edition by
Anthony J. Leggett, University of Sussex
FRONTIERS IN PHYSICS SERIES, NO 48

This unique book, written by a leading Soviet theorist, is not a textbook of quantum mechanics but rather a compendium of the "tricks of the trade" which all practicing theoretical physicists use, but few have tried to set down systematically in writing. The emphasis throughout is on the development of qualitative feeling for problems through the use of order-of-magnitude estimates, simplified models and symmetry considerations.

Contents: Dimensional and "Model" Approximations. Various Types of Perturbation Theory. The Quasiclassical Approximation. The Analytic Properties of Physical Quantities. Methods in the Many-Body Problem. Qualitative Methods in Quantum Field Theory.

1977, xxiv, 440 pp, illus
Hardbound ISBN 0-8053-7064-1 \$21.50

COMPUTATIONAL PROBABILITY AND SIMULATION

Sidney J. Yakowitz, The University of Arizona
APPLIED MATHEMATICS AND COMPUTATION SERIES, NO 12

From the Preface

"The intention of this textbook is to share with the reader an experimental approach to studying the facts and models of probability theory while introducing him to principles of probabilistic simulation. (It is) a valuable complement or supplement to a course in probability. Additionally, *Computational Probability and Simulation* will be useful to persons who wish to acquaint themselves with simulation technology."

Contents: Random Processes and Random Number Generators. Simulation of Probability Experiments. Gaming, Random Walks, and Linear Equations. Gambler's Ruin with Extensions to Inventory Control. Limiting Processes for Random Walks and Time Series Simulation. Monte Carlo Integration and Solution of Differential Equations. Index. (Exercises and references for each chapter).

1977, xxii, 240 pp, illus
Hardbound ISBN 0-201-08892-4 \$22.50
Paperbound ISBN 0-201-08893-2 \$12.50

WILEY INTERSCIENCE

VARIABILITY OF THE OCEANS

by **A. S. Monin, V. M. Kamenkovich and V. G. Kort**, all of *Shirshov Institute of Oceanology, USSR Academy of Sciences*.
Translated from the Russian; edited by **J. L. Lumley**.

Describes all the major nonstationary processes in the ocean and systematically reviews observational data and current theories. Discusses the variability of the ocean in relation to the various areas of the economy and to the development of long-term weather forecasting; sets forth the mechanism of the air-sea interactions; classifies nonstationary processes and analyzes their observational methods; and examines the prospects for studying the variability of the ocean, based on worldwide observations and numerical modeling.

0471 61328 2 256 pages June 1977 £14.95/\$25.35

ACOUSTICAL OCEANOGRAPHY Principles and Applications

by **C. S. Clay**, *University of Wisconsin*, and **H. Medwin**, *Naval Postgraduate School*.

Develops principles of sound propagation and applies them to the practical use of sound in the sea. Contains basic information on mechanical wave propagation in fluids as well as more advanced discussions of acoustic studies of marine life and the ocean floor. Ten appendixes provide further details on topics discussed in the text. (Ocean Engineering: A Wiley Series)

THE UNDERWATER HANDBOOK: A Guide to Physiology and Performance for the Engineer

edited by **C. W. Shilling, M. F. Werts and N. R. Schandelmeier**, *Department of Medical and Public Affairs, George Washington University*.

The aim of this book is to provide a comprehensive account of all types of underwater activity. It is written so as to be understood by the non-scientist; it will be particularly useful to the engineer in the development of new types of equipment and to the diving supervisor in knowing what can be expected in manned machine complexes working in either a hyperbaric environment or underwater.

0471 99453 7 940 pages May 1977 £40.00/\$80.00

Available from Wiley Ltd., in the U.K., Europe, Middle East (excluding Israel) and all of Africa.

LIGHT IN THE SEA

edited by **J. E. Tyler**, *Scripps Institution of Oceanography*.

Brings together significant published material that has appeared in journals, expedition reports, and private printed documents concerning the study of light in the sea. Presents research results relating to the interaction of radiant energy with water and the scientific methods used for understanding this interaction. (Series: Benchmark Papers in Optics Vol. 3)

0470 99143 7 approx. 400 pages In Press
approx. £22.50/\$38.10

HANDBOOK OF HYDROLOGICAL STUDIES IN OCEANS AND SEAS

Editor-in-Chief: **I. M. Soskin**, *Central Board of the Hydrometeorological Service for the USSR Council of Ministers, State Oceanographic Institute*.

Translated from the Russian.

For some decades the furthest reaches of the seas and oceans, from the poles to the equator, have been penetrated in order to measure, observe, and record marine characteristics like temperature, current salinity, and wave action. This classical account of Soviet methods, which accentuates the practical, instrumental aspects of oceanography also includes a detailed analysis of the post-cruise processing and analysis of the data.

07065 1576 5 approx. 370 pages In Press
approx. £27.50/\$45.10

An IPST publication distributed by John Wiley & Sons Ltd.

MARINE SEDIMENT TRANSPORT AND ENVIRONMENTAL MANAGEMENT

edited by **D. J. Stanley**, *Smithsonian Institution*, and **D. J. P. Swift**, *Atlantic Oceanographic and Meteorological Laboratories*.

A systematic application of principles of sedimentation to modern problems of marine environmental management. Describes principles of continental margin sedimentation and the effect of man-made structures on sedimentation processes.

0471 02540 2 620 pages July 1976 £25.20/\$44.10

John Wiley & Sons Ltd · Baffins Lane · Chichester · Sussex · PO19 1UD · England

crisis quite unlike that ever faced by any other science. Ocean processes and living resources do not respect boundaries arbitrarily imposed by man, and scientists are finding that their floating laboratories can no longer be sited where they are needed, nor do they have unrestricted access to areas where they can collect the data that are essential for their research work.

This is inevitable during the transitional period, that is, the duration of the Conference, and it will doubtless cause a temporary withdrawal to accessible areas—to waters under the jurisdiction of like-minded coastal states and to the deep oceans, though the legal status to be accorded the deep ocean floor and subsoil is still under discussion.

There is every indication, however, that coastal states have been stimulated by the Conference on the Law of the Sea and the number of enquiries and requests from developing coastal states for help in building up their marine science infrastructures is growing to flood proportions. Countries are turning in increasing numbers for direct help by bilateral aid and to such bodies as Unesco, OECD and the EEC.

In the long term therefore, it is already abundantly clear that there will be no insurmountable restrictions on the marine sciences. The length of the present hiccup will depend entirely on the perception of scientists in the limited number of countries with developed and sophisticated marine science infrastructures, and their willingness to help other coastal states to develop their expertise and capabilities as part of their on-going marine science programmes, and not as a separate exercise which is always the responsibility of another government department.

Economic zone and beyond

The great majority of participants at the Conference are now agreed (as noted in the preceding article) that the territorial sea should be increased in width to 12 miles and that there should be an economic zone of 200 miles width (from the coast) over which coastal states would virtually have complete sovereignty so far as living and non-living resources are concerned. Furthermore, where the geographical continental shelf extends more than 200 miles offshore, the coastal states will still have the same sovereignty, though a proportion of the profits from exploitation of resources in this extended area may have to be used for the benefit of developing countries. The single most important matter of concern to marine scientists is the almost unanimous wish of the developing countries to insist on scientific research and exploration in these areas being placed in the same category as exploitation of resources, an activity that can only be carried out with the consent of the coastal state. This attitude is due to the not unfounded belief that knowledge of the existence of resources leads to a position of power and a very well founded fear that research ships do not always confine their activities to the project declared and may be collecting data detrimental to the coastal state, coupled with the fact that it is well known that military and commercial interests are in most countries given precedence over those representing scientific research.

The 200-mile width chosen for the economic zone is an arbitrary figure based originally on claims made (and still maintained) by a number of South American countries for the width of their territorial sea. This had nothing to do with the geographical concept of the continental shelf (which had been the basis of the rights of national jurisdiction contained in the 1958 convention, on the principle that the continental shelf is an extension of the continental land mass) but rather was based on the economic need of developing countries on the west coast of South America to lay claim to what was then developing into the greatest fishery resource in the world.

There is no question, however, but that the deployment of scientific research ships in the strip of ocean 200 miles in width from the coast and beyond that distance to an as yet undefined limit which will certainly be in the deep ocean, will be firmly under the jurisdiction of the coastal states. The most likely contender for this outer limit seems to be the outer edge of the continental rise but this is so ill-defined in most oceans that it will remain a theoretical limit rather than one that can be plotted on a chart, for many years to come.

Where the limits can be drawn in without too much difficulty, and future jurisdiction is reasonably clear, is in the regional seas, in particular the North Sea, Baltic, Mediterranean, Caribbean, South China Sea, etc., where the whole sea will virtually be under the jurisdiction of the coastal states.

In the Mediterranean, for instance, this situation has already been recognised quite clearly by the coastal states of the region, and they have retained for themselves the right to formulate all policy regarding research on the marine environment being developed under the auspices of the United Nations Environment Programme (UNEP). This does not, however, prevent states from outside the region, in particular developed countries with research ships and appropriate expertise, participating in the implementation of such research projects.

Prospect for more cooperation

At first glance this might seem to mean that the only research work that will be permitted in such a region and off the coasts in the open ocean, will be that having immediate application to the problems and interests of the coastal states and, as many of these states will be developing countries with little interest in sophisticated research, the outlook may superficially look bleak for fundamental and other scientific research work having wider implications than a purely local interest and application. But this ignores the basic bargaining power in the hands of the developed countries of trained manpower and ships which, if used properly, will allow both parties to obtain what they need: the developing countries—training and education in the marine sciences, experience and strengthening of their infrastructures, and the developed countries—the right to work in areas of scientific interest. Such an arrangement will only work if each party recognises the interests of the other and is prepared to cooperate closely to their mutual benefit.

This calls for three quite separate types of international education to meet the changing situation.

- (1) Education of scientific administrators and decision makers in developing coastal states to enable them to understand the peculiarities inherent in the administration of marine science.
- (2) Education of senior scientists and scientific funding agencies in developed countries to get them to face up to the changing situation and abandon their rearguard action for freedom of scientific research and separate definitions (and therefore regimes) for fundamental and applied research.
- (3) Education and training of young marine scientists in developing countries to build up the national infrastructures and know-how in these countries, so as to educate out the suspicion now so rife in the UN Conference on the Law of the Sea and in national dealing between developed and developing coastal states.

Let us take these three basic requirements and look at them more closely. (1) The second half of the twentieth century is the era of 'development'. The United Nations Development Programme has been established and many developed countries have set up development agencies to provide aid to developing countries. Such agencies usually

work through bilateral agreements, sometimes using the UN specialised agencies in the process. At the same time, the developing countries are clamouring for what is known as 'transfer of technology', as if technology consists of something that can be handed over in the form of a package bringing immediate affluence to the recipient. In fact, much of the money poured into 'development' over the years has been wasted due to two basic factors: first, lack of basic research before the actual development project is started; and second, inadequate training of personnel in the developing country to enable the project to be undertaken in the first place using local skilled personnel and, even more important, to ensure that the activity whatever it may be, continues in full operation when the basic project is complete and external support, both in the way of funds and personnel, is withdrawn.

This is just as applicable in the field of marine science, and marine affairs generally, in which the real lack of most developing countries is not technology as such and frequently (particularly in recent years) not even funds, but trained personnel and a viable infrastructure bringing together all the various interests—universities, navy, fisheries, basic research interests, marine engineering and so on.

Once an educational system has been devised that will produce a regular supply of trained personnel on the market, a country is able to absorb outside technological know-how and adapt it to its national needs. In the field of marine science, the best example of a developing country whose administrators and decision makers have realised this truth, is Mexico which is well on the way to becoming self-sufficient in marine scientific manpower and therefore a very powerful nation in marine affairs generally.

There is a real need to educate scientific administrators and decision makers in developing countries to the fact that there is no short cut to the wealth of the ocean's resources and that their highest priority should be the development of a cadre of trained manpower.

(2) There is no doubt that coastal-state control over scientific research in the economic zone is here to stay but there are far too many senior scientists unable to assimilate the fundamental political changes that have taken place in their chosen area of activity. Fighting the inevitable can do more harm than good as it can only strengthen the belief, sincerely held in many countries with no fundamental scientific background, that scientific research in the oceans is a cover up for other activities which would be to their detriment.

In the past, senior scientists planning research cruises have as a concession offered a few places aboard ship during a cruise to one or two scientists from the coastal states off which they wish to operate. Developing country scientists that have participated in such cruises have almost unanimously declared that they have been valueless both to themselves and to their country, as they have come unprepared to a sophisticated activity run by a research group having close personal relations and a full knowledge of the work being conducted; as a result, they have found themselves as outsiders with little understanding of what is going on.

In the future it must be recognised that the research is being conducted in what is virtually the national territory of the coastal state, just as if it were taking place on that part of the country which is above water. As a result the coastal state, through its marine scientists, now has the full right to participation in the research project from start to finish. This means that the coastal state scientists must be fully involved in the project from the first planning stages, through the data collection/cruise phase, to the data analysis phase and the assessment and writing up of the results. Should it be more convenient,

due to availability of facilities, development of equipment, and so on, to carry out the first and last phases in a laboratory in a developed country, for example of, that providing the research vessel, this is where the developing country scientists will have to work at full cost to the developed country. In fact the trend should be towards developed country scientists setting up facilities in developing country laboratories (at developed country expense), in order to help developing countries to strengthen their own facilities.

Whilst the developed country scientists have got to recognise the essential change in their working conditions if their science is not to die, the scientific funding bodies and aid agencies must come to realise that they are in this together and that this is a joint activity within the mandate of both bodies. The first reaction of a well known funding agency to such a suggestion was "we cannot afford it" and no doubt initially aid agencies would have a similar reaction against what they would consider to be funding national research projects, even if in the waters of countries they are set up to aid. Such attitudes must be modified drastically in the recognition that this is not only to the benefit of both in the long term but is basically the only solution if global marine science is to survive. A logical development would be to bring the two activities under the same administration and no doubt this will be the final outcome in many countries, but such moves will clearly only come about in slow time.

(3) Finally, there is the widely recognised need for basic education and training of young marine scientists in the developing countries (as touched upon in (1) above).

There are many difficulties inherent in the development of a viable infrastructure in a country with little or no tradition in the marine sciences, such as wastage and 'brain drain', which would be out of place if discussed in this article, but building up a strong cadre of marine scientists in each coastal state is the only way of overcoming the almost pathological aura of fear and suspicion that has grown up in many developing countries with regard to marine scientific research. It will only be when countries have their own trained scientists to whom the politicians can turn for advice, or, even more important, who can apply pressure on the politicians to take action, that this fear and suspicion will subside. The intergovernmental bodies will have a growing role to play in this regard if they can be so structured to gain the trust of the developing countries but they can never replace a strong national cadre of trained marine scientists.

It will be noted that education and training of marine scientists in developed countries has been omitted from this list. This is because it is considered to be a national problem for the developed countries concerned. It must however be clearly recognised, and soon, that education and training of marine scientists in developing countries is an international problem requiring urgent and greatly increased action.

Bright future?

I am convinced that the future for the marine sciences is bright but that this will depend on two basic factors: first, the end of the UN Conference on the Law of the Sea and a stable period during which the results and implications thereof can be assessed and put into practice; and second, the recognition and acceptance of a new and very different international regime for marine science in the future, by those who have been brought up to believe in their historical right to conduct marine scientific research where and when they please (subject only to finance). When these two factors have been met, such a regime could lead to accelerated progress in the marine sciences through a greatly enlarged global community of scientific colleagues working towards common scientific goals.

1967-77: Ten years of marine geology and geophysics

Xavier Le Pichon

CNEXO, B.P. 107, Paris 75116 and COB, B.P. 337, 29273 Brest, France

Plate tectonics gave a great stimulus to marine geology and geophysics; in the years since its enunciation there have been major drilling programmes, a new science of global palaeoenvironmental oceanography and much more detailed oceanographic surveys. The pace shows no sign of slackening—in the next few years the passive continental margins will be much studied.

In April 1967, Jason Morgan¹, having unexpectedly changed the subject of his talk, demonstrated to a large audience at the American Geophysical Union meeting, in Washington, how sea-floor spreading in the Atlantic Ocean had occurred between two rigid 'crustal blocks' moving apart on the surface of the spherical earth. This 'plate tectonics' model of the Earth's surface was implicit in the sea-floor spreading hypothesis of Hess², with its two corollaries of Vine and Matthews³ magnetic lineations and Tuzo Wilson⁴ transform faulting. But although the magnetic anomaly profiles across the East Pacific rise had convinced many earth scientists by early 1966 of the reality of sea-floor spreading, the demonstration made by Morgan was largely ignored by the audience. It is only during the following years that the full impact of rigid plate kinematics led to the present revolution in the Earth sciences. And this revolution has been most spectacular in marine geology and geophysics, which, with earthquake seismology, furnished most of the discoveries on which it is based.

It is in the field of global kinematics, past and present, that the progress has been most rapid. Because plates are rigid, it has been possible to construct a fairly precise global quantitative model for the present interaction of the 11-12 major plates, along their boundaries which are generally covered by several kilometers of water. In addition, it has been possible to decipher, at least in a preliminary way, the complex kinematic history of all large oceans, through the powerful Vine and Matthews method of dating the igneous oceanic crust. Thus, for the first time, there is a successful quantitative model of the dynamic evolution of the earth surface, a model which has been repeatedly tested, in particular through the use of deep-ocean drilling.

Deep-sea drilling

In 1968, at the time when the plate tectonics model was being accepted by the scientific community as the working model, the D. V. Glomar Challenger set out to drill her first hole through the floor of the Gulf of Mexico. She is now drilling her 418th hole and the results⁵ obtained by the Deep Sea Drilling Program (DSDP), under the sponsorship of JOIDES (Joint Oceanographic Institutions for Deep Earth Sampling) have shown that the proposed kinematic evolution of the oceans is supported by the analysis of the sedimentary column and the underlying igneous crust. In particular, the magnetic reversals absolute timescale, which is the basic tool to unravel the history of the oceans and which is now known from present to Middle Jurassic (165 Myr ago) with a relatively good precision (≈ 10 Myr), was entirely calibrated by deep-sea drilling results.

The single most important accomplishment of deep sea drilling, however, was the creation in the last 3-4 yr of a new field of science—global palaeoenvironmental oceanography. This occurred as it was progressively realised that the drastic changes in the Earth surface configuration are highly correlated to changes affecting the hydrosphere and the atmosphere, but also the biosphere. It now seems possible to obtain reasonable physical models which broadly account for the deterioration of climate during the last 40 Myr, simply by taking into account the different ocean-continent distribution pattern (for example, ref. 6).

Palaeoenvironmental oceanography

In the last 200 Myr the Earth surface configuration has changed from a supercontinent, Pangea, surrounded by a proto-Pacific super-ocean, Panthalassa, to the present fragmented ocean and dispersed continents. Panthalassa had a western prolongation, called Thetys, inserted like a wedge between Eurasia to the north, and Africa, India and Australia to the south. Its margin was almost entirely a consuming plate boundary where oceanic lithosphere was being subducted under the continent. Very little is known about its palaeo-oceanography as most, if not all, of the Triassic (~ 200 Myr) lithosphere has since returned into the mantle. Future drilling may, however, obtain Lower Jurassic sediments from the oldest portion of the Pacific ocean, which is now in the process of disappearing along the western consuming plate boundary, thus providing essential data on Panthalassa.

There is much better information on the evolution of the world ocean during Mesozoic, 165-60 Myr ago, which was characterised by ocean basins in an early stage of evolution, the newly born Atlantic and Indian basins, by a mature but shrinking proto-Pacific and a disappearing Thetys. The breaking up of Pangea resulted in the creation of rifted inactive margins where a great proportion of the Earth's sediments have now been trapped, bordering shallow (≈ 3 km) and narrow basins underlain by hot oceanic lithosphere. The ocean environment under an equable climate, was fairly tranquil with thermo-haline homogeneity and mostly latitudinal, probably wind-controlled circulation pattern (for example, ref. 7).

The new ocean basins continuously widened but also deepened, as they became older. The relationship between ocean-depth and age of the plate is a direct consequence of the lithospheric plate being a thermal boundary layer which moves away from its zone of creation at the axis of the mid-ocean ridge. It is a powerful tool to reconstruct the palaeobathymetry of a given ocean, knowing its age.

This age-depth relationship also implies that the average depth of the world ocean is related to its average age. Thus a faster rate of lithosphere renewal should lead to overflow over the continental borderlands, and vice versa. This effect may be the principal cause of the worldwide transgressions and regressions, outside of the geologically relatively recent changes in the volume of the ice-caps. The well known Upper Cretaceous (80 Myr ago) transgression, during which 85% of the Earth was covered by water (compared with 71% today and 65% during the largest regressions), has been explained in this way⁸. In any case,

Then.....

.....and now

A General Bathymetric Chart of the Oceans was first published in 1903 by Prince Albert of Monaco. The upper picture shows a portion of the 1938 edition for the Indian Ocean just east of Somalia (1,400 × 900 km). This chart was still in use at the beginning of the International Indian Ocean Expedition in 1959. The 1975 edition (lower) shows the same area as now charted. The Carlsberg Ridge is now seen to run into the Owen Fracture Zone. Contours are at 1,000 m spacings; ship's tracks are marked lightly.

recent oceanographic, mostly oil-applied research, has demonstrated the existence on the continental margins of numerous global unconformities which are related to sea-level changes. It now seems possible to reconstruct a fairly precise history of the evolution of sea level during the last 200 Myr.

The radical change brought by the Cainozoic (<60 Myr) era, which transformed the warm ocean and mild climates

of the Mesozoic into the cold ocean and glacial climates of the Quaternary (<3 Myr) has been described as a 'commotion in the ocean'. The most dramatic change occurred 38 Myr ago with a drop of about 10 °C of the deep water temperature⁹. This was related to the formation of a circumantarctic seaway, with separation of Australia from Antarctica and the opening of the Drake passage, and to the closure of the Tethys. Strong thermo-haline deep

THE MARINE ENVIRONMENT

Volume 5 in the series *Environment and Man*, edited by John Lenihan and William W. Fletcher.

This book looks at the sea as a vast environmental laboratory from which we have much to learn. Production and pollution, the main issues in managing it, are the essential themes of this volume.

Ocean Yearbook

A new publication for the review and evaluation of major ocean issues

At present, no existing periodical systematically collects and interprets data on the burgeoning economic, political, social, and scientific significance of the world's oceans. **Ocean Yearbook** is intended to fill that gap.

Each annual volume will be divided into the following categories, and contributors will examine issues and developments under each heading:

<i>review of the year</i>	<i>living resources</i>
<i>non-living resources</i>	<i>regional developments</i>
<i>marine science and technology</i>	<i>environment</i>
<i>coastal management</i>	<i>military activities</i>
<i>transportation and communications</i>	

The inaugural volume, consisting of over 500 pages, will include, among other scholars:

<i>Sidney Holt</i>	<i>T. V. R. Pillay</i>
<i>Edward Symonds</i>	<i>Peter Odell</i>
<i>Roger Charlier</i>	<i>R. A. Ramsay</i>
<i>Konstantin Fedorov</i>	<i>Peter Thacher</i>
<i>Geoffrey L. Kesteven</i>	<i>Francis Auburn</i>

writing on such subjects as:

<i>fisheries</i>	<i>aquaculture</i>	<i>arms control</i>
<i>The Southern Ocean</i>	<i>the health of the oceans</i>	
<i>offshore oil and gas</i>	<i>economics of shipping</i>	

Editors: Elisabeth Mann Borgese and Norton Ginsburg

Sponsor: International Ocean Institute (Malta)

Publication: Annually in hardcover

Special prepublication discount

Order form

Complexes & First Row Transition Elements

D. NICHOLLS

An introductory text for students making their first detailed study of transition element chemistry. It concentrates on the first member of each group, since their properties differ significantly from those of subsequent members. The first part of the book deals with the chemistry of complexes—a topic of central importance to the study of transition elements. Throughout the text emphasis is placed on the properties and reactions of metal aquo-ions and the donor-acceptor properties of transition metal compounds.

£3.95 paperback

The Heavy Transition Elements

S. A. COTTON AND F. A. HART

A detailed account of all the transition elements except the first row (3d series). The book features a discussion of lanthanides and actinides, with emphasis on recent advances in their structural chemistry.

hardcover £8.95 paperback £4.95

For further details and inspection copies, please write to Rosemary Hamilton (N), The Macmillan Press, Little Essex Street, London WC2R 3LF

circulation became well developed, resulting in widespread sea-floor erosion and the present meridional as well as latitudinal circulation pattern was established at this time.

But, it is still not understood why, whereas the first sea-ice appeared 38 Myr ago, the Antarctic ice-sheet did not develop for another 20 Myr. As for the Arctic ice-sheet, it started to develop 3 Myr ago and this event may be related to the creation of the Central America land bridge. The history of the repeated Late Pliocene–Pleistocene (<3 Myr) southward transgression of polar water by as much as 20° of latitude is now being very precisely reconstructed. One can expect in the years to come major progress in the understanding of this Cainozoic ‘commotion’ from such ocean sediment studies and from oceanologic and climatic modelling.

Geochemistry and geology

The role of the world ocean as a geochemical sink is also being progressively revealed. The degree of oxygenation of the deep ocean has greatly changed. It seems to have been mostly poorly oxygenated during Mesozoic whereas it is highly oxygenated nowadays. These changes probably deeply affected the carbon cycle in the hydrosphere and the carbon dioxide contents of the atmosphere. The development of calcareous and siliceous microorganisms during the Mesozoic must also have introduced a basic change in this geochemical complex cycle.

In contrast, there has been relatively little progress in our understanding of the geological structures generated or modified by the processes of plate tectonics, and first the oceanic lithosphere itself. A striking example concerns its upper portion: the oceanic crust. We know its age nearly everywhere but we still do not know unambiguously its structure and composition. Fifteen years ago, marine geophysicists had proposed, on the basis of seismic refraction results, that the oceanic crust had a homogeneous and uniform three-layer stratification (1, sediments; 2, basement; 3, ‘oceanic layer’) on top of the upper mantle. Layer 2 was supposed to be made of basalt and layer 3 of gabbro. Hess later proposed that layer 3 consisted instead of serpentinised peridotite. Today, the controversy is still not resolved. The oceanic crust models proposed nowadays are partly based on the results of scattered, poorly located dredgings out of a precise structural frame work but they mostly draw on analogies with ophiolites and predictions based on highly simplified theoretical models.

To this day, drilling has failed to shed much light on this problem because of technological limitations. The largest penetration in the igneous crust does not exceed 600 m,

that is about one tenth of the thickness of the crust. In addition, the necessity to dispose of a least 100 m of sediments over the igneous crust to stabilise the drill bit excludes most of the actively accreting boundaries from being sampled. Consequently, no direct information can be obtained on the actual processes of formation of the crust by drilling. It is fair to conclude that our poor knowledge of the oceanic crust results from the scarcity of direct geological evidence.

An important development, in this domain, has been the introduction of a much more refined seismic refraction investigation of the ocean crust and lithosphere, with ocean bottom seismographs (the so-called OBS) and better inversion techniques. The resulting acoustic structure is apparently quite complex and variable, as would be expected. Layer 2 seems to be a zone of strong velocity gradient with an uppermost very low velocity zone which progressively disappears with age. There is no generally accepted standard structure for layer 3 and its evolution with age, although it has recently been proposed that a rapid thickening away from the rise crest is due to the formation of a low velocity zone at its base. There is some fairly strong evidence for the existence of a magma chamber at a depth of 2 km below the sea floor under the East Pacific rise¹⁰. No such magma chamber could be detected under the crest of the slower spreading mid-Atlantic ridge.

Very long seismic refraction lines and earthquake seismological studies (primarily surface waves) have given some important information on the structure and evolution of the lithosphere with age. If the thickness of the lithosphere is defined by the lid of the underlying low velocity zone, there is a definite thickening with age from less than 50 km to 80–90 km. In the accretion zone, under the crest of the mid-ocean ridge, where the lithosphere is being created, a zone of partial melting comes within a small distance from the sea floor. Strong internal stratification seems to be common within the lithosphere.

Although this whole field of direct modern investigation of the structure and evolution of the crust and lithosphere by explosion and earthquake seismology is very promising, it is still in its infancy and it is too early to make firm conclusions. Note that an interesting new technique may well be the use of commercial multi-channel seismic reflection for recording oblique reflections from the crust and mantle. Another important new technique will certainly be the use of seismic receivers in the deep-sea drilled holes.

In the absence of detailed direct measurements, physical models based on plate tectonic concepts could bridge the

Mechanical arm of CNEXO submersible CYANA sampling a piece of pillow at 2,700 m depth in Transform Fault A in the Atlantic Ocean during the FAMOUS project. Part of a vertical dyke is seen in the background and numerous signs of animal life.

gap in our knowledge. It is true that it is relatively easy to explain heat flow and water depth variation as a function of age (see ref. 11, for example). But, this success does not mean that the formation of the oceanic crust and lithosphere is understood. Most of the proposed models are purely thermal and ignore the mechanical definition of the lithosphere. Further, widely different sets of parameters can be chosen, provided that the principle of a rigid thermal boundary layer is preserved. And, most important, their results away from the axis do not depend on the mode of transfer of material from the asthenosphere to the lithosphere in the rather narrow accreting zone. Yet, the knowledge of this mode of transfer is essential to any modelling of the formation of the lithosphere and crust. Clearly, additional constraints are needed. An interesting new one has recently been shown to be that the ocean depth does not increase as fast beyond 60–80 Myr as would be required if it were the cooling of a thermal boundary layer, which indicates the existence of additional sources of heat.

Thus, our knowledge of the ocean crust and lithosphere structure is still schematic. Is there a clearer understanding of the geological structures created by the interaction of plates along their boundaries? In fact, most of the geological models proposed for a consuming plate boundary (deep-sea trench), for an accreting plate boundary (spreading centre), or for a transform boundary are in great part hypothetical and grossly simplified.

Yet, approximately 120,000 km of length of plate boundaries lie below 2.5–11 km of water, which have no equivalent or directly comparable tectonic features above sea level. This is about 80% of the total length of the boundaries of the well defined plates. It is along the oceanic accreting boundaries that the tectonic fabric of the ocean floor is created. It is along the oceanic consuming boundaries that some of the tectonic fabric of the future subaerial mountain belts is presumably set into place. An understanding of the process of formation of the oceanic crust requires knowledge of the spatial and temporal distribution of the volcanic and tectonic events leading in turn to a full comprehension of the pattern of geochemical variation within the accreting plate boundary area. An understanding of the process of subduction also requires a knowledge of the spatial and temporal distribution of the tectonic features within the consuming plate boundary area and this, in turn, can lead to important information on the rheology of the plate itself. Clearly, any coherent development of the plate tectonic model passes by an adequate study of these boundaries.

FAMOUS

Standard oceanographic techniques currently used by most investigators are not adequate for this type of detailed geological and geophysical surveys as they have a spatial resolution which is not much better than half of the water depth. As a result, so-called detailed surveys often have a grid spacing of 10 km or more. Yet, studies of magnetic anomalies using precisely navigated deep-tow studies, have shown that the width of the zone of creation of oceanic crust in accreting plate boundaries is 2–6 km. To resolve processes occurring on such a scale, one needs to use techniques having a much better resolution with very precise navigation. These techniques should of course include bathymetry, seismic refraction survey and detailed geological surface mapping with precisely located multiple drillings. Such a complete study has not yet been performed. The FAMOUS program has made an important step in this direction^{12–14}, however.

The French American Mid-Ocean Undersea Study (FAMOUS) was designed 'to conduct an integrated and detailed geological, geophysical and geochemical study of a portion of plate boundary where new oceanic crust is generated' in the North mid-Atlantic ridge. The main

characteristic of this study is that, for the first time in deep ocean, object having a size from a few centimetres to kilometres were mapped and placed within the framework of a precise structural context. This was done in a first phase with the help of precisely navigated surface ship studies using the powerful multi-narrow beam echo-sounder, deep-tow fish and transponder located dredges and bottom photographs. Then, in a second phase, precisely navigated manned research submersibles established well documented geological sections, with both tectonic observations and rock sampling. Thus, methods of classical field geology could be applied to the deep ocean floor. As a result, a precise structural and petrological model of the Rift Valley and intersecting transform fault has been obtained for the first time.

But FAMOUS was just a beginning. There is little doubt that future research will rely more and more on studies with the same amount of resolving power, from seismic refraction to field geology. A good example is the problem of hydrothermal circulation in newly formed oceanic crust which has been shown to have a major role in the cooling of the crust, the distribution of heat flow, the formation of mineral deposits leached from the crust and the general geochemical cycle of seawater. The vents through which hot water comes to the sea-floor have such a small size that they require high-resolution techniques to be studied. The research submersible Alvin is now making such a study on the Galapagos rise, in the Eastern Equatorial Pacific ocean.

Perhaps, because of the formidable depths at which they lie, consuming plate boundaries have been studied in less detail¹⁵. However, a great step forward in their exploration was made with the acquisition of good commercial seismic reflexion lines revealing the structure of the inner wall which actually consists of a sedimentary accretionary wedge, made of imbricated thrust sheets which is several tens of kilometres long and up to tens of kilometres thick. The actual process of formation of this complex wedge is still not well understood and may include alternating phases of erosion and accretion. It has even been proposed that considerable erosion of continental crust may occur. The importance of such processes in an understanding of the geodynamics cannot be over emphasised.

The future

The next 2 yr, which will see the first systematic attempts at drilling consuming plate boundaries, should shed considerable light on these problems. But a much greater effort is needed to resolve their detailed structure and tectonics. For example, the detailed pattern of microseismicity across a trench is still essentially unknown, although a few OBS measurements have been made.

It is quite probable, however, that, in the next 4–5 yr, the greatest effort of the marine geoscience community will go towards solving the structure and evolution of passive continental margins which contain, as mentioned above, up to 50% of all the Earth's sediments. In addition to their potential economic interest, the passive continental margins are probably the only places where one can find the record of the early stages in the formation of a new ocean. There is still considerable disagreement on such fundamental problems as the nature of the continental crust—ocean crust transition, the actual boundary of the original continent, the processes which have allowed the thinning of the continental crust and the relative importance of the possible processes of subsidence. The ultimate tool for this type of investigation, very deep drilling, is actually being actively considered in spite of the very large costs involved.

For this review to have been truly complete, many other results as well as planned investigations would have had to be mentioned. In addition, no single writer can possibly cover adequately such a large field, so this review is certainly somewhat biased. There is, however, little doubt that the large scale exploration phase of the world ocean

made in the framework of plate tectonics in the last 10 yr is now coming to an end. The next phase will require much more elaborate, more costly techniques, having a greater resolving power to lead to a correct modelling of the various physical and chemical processes involved in the functioning of the great lithosphere engine.

Breaking waves

E. D. Cokelet

Institute of Oceanographic Sciences, Wormley, Godalming, Surrey, UK

Why do waves break? What happens during breaking itself? More than a hundred years of mathematical studies still leave some aspects of these questions unanswered, although we are now understanding much about the processes leading up to breaking and the period after breaking has occurred.

BREAKING waves, both whitecaps and surf, are commonly observed in the ocean, but surprisingly little is known about them. Yet they are important for a variety of reasons. They place large hydrodynamic loads on man-made structures, transfer horizontal momentum to surface currents, provide a source of turbulent energy to mix the upper layers of the ocean, move sediment in shallow water, and enhance the air-sea exchange of gases and particulate matter. To further our understanding of these processes we must first understand the dynamics of wave breaking.

The scientific study of breaking waves is difficult for a variety of reasons. In theoretical investigations the equations of motion are nonlinear, and the boundary conditions (also nonlinear) must be applied at the free surface whose location is not known beforehand but must be determined as part of the solution. Observations are hindered because breaking occurs rapidly and intermittently. In the ocean large wave forces tend to carry away the instruments; whereas measurements made in controlled laboratory conditions cannot always be scaled-up owing to the relatively greater importance of viscosity and surface tension at the small scale.

At the present stage of theoretical development simplifying assumptions are commonly made about the flow-field in a wave. The dynamics of ocean waves are dominated by the inertia of the fluid, the pressure gradient, and the acceleration of gravity. For large scale waves the fluid viscosity can be neglected in the bulk of the fluid since it is important only in very thin layers near the fluid boundaries. Similarly, surface tension usually can be neglected unless the free surface is very highly curved. It is mathematically convenient to assume the fluid to be irrotational, that is, to have no vorticity—a measure of the rotation which an individual element of fluid has about its centre. This will be true if a wave propagates into a region of inviscid fluid previously at rest. It will always be a very good approximation unless there is a strong current shear or the flow becomes turbulent. In the latter case the fluid can still be irrotational outside the turbulent zone. The mathematical simplification is considerable since in an irrotational wave the vector velocity may be expressed as the gradient of a scalar (the velocity potential function) for which a linear equation (Laplace's equation) holds. We can neglect the airflow above the water since the density of air is 10^{-3} times that of water. Finally it is useful to consider the flow to be two-dimensional, that is, to neglect variations in a direction parallel to the wave crest. As more is

learned about the wave motion the effects of these neglected quantities can be incorporated.

It will be helpful to review some of the properties of simple waves which do not break. A wave is characterised by its wavelength (λ), water depth (d) and wave height (H , see Fig. 1). It is not the absolute values of these quantities but their ratios which are important. When the water depth is greater than about half of a wavelength the wave is in deep water, and it does not feel the effects of the bottom. Smaller values of d/λ correspond to shallow-water waves, and in the limit when d/λ approaches 0 a solitary wave exists, so-called because it consists of a solitary crest moving in shallow water with troughs infinitely far away. Many of the simple properties of non-breaking ocean waves can be explained in terms of linear, small-amplitude theory which is an approximation to the complete theory of wave motion valid when the wave steepness (H/λ) and height-to-depth ratio (H/d) are much less than 1. In deep water when a small-amplitude wave passes, individual particles of water do not travel along with the wave, but instead they move in closed circular orbits whose radii decrease exponentially with depth as shown in Fig. 1. In shallow water these trajectories become ellipses with shortened vertical axes, and for a solitary wave each fluid particle moves forward with a hop as the wave passes. The profile of a small-amplitude wave is symmetric about the vertical line passing through its crest.

Research work on breaking waves can be divided into three categories: those concerning waves (1) before, (2) during, and (3) after breaking. In this review we shall concentrate on some of the latest results in the first two categories.

Fig. 1 The profile of a small-amplitude, sinusoidal wave in deep water showing the circular orbits of fluid particles with arrowheads indicating the direction of water movement at various locations. The rapid decrease of the orbital radii with depth is illustrated beneath the crest. The wave of wavelength λ (the horizontal distance between successive troughs or crests) and height H (the vertical crest-to-trough distance) is moving to the right at speed c with gravity g providing the external restoring force. (This wave is too high relative to its wavelength for small-amplitude theory to hold, but it was drawn this way for purposes of illustration).

Fig. 2 A close-up view of the crest of the highest, steady wave as seen from a reference frame moving with the wave to the right. Fluid particles come to rest at the sharp wave crest.

Before breaking

One approach to the study of breaking waves has been to start with a small-amplitude wave and to consider progressively higher symmetric waves which propagate without change of shape in water of constant depth. For a fixed wavelength and depth there exists a highest wave which is just on the verge of breaking. When viewed from a reference frame moving with the wave the flow is steady, that is, independent of time, and this simplifies the problem. Analytically it is possible to begin with the small-amplitude approximation to the fluid motion and to correct this for the effects of increased wave height. This is then recorrected and so on until sufficient accuracy is obtained. Each successive correction may be thought of as one member in an ordered series of corrections called a perturbation series. The importance of any correction relative to the one before it is measured by a perturbation parameter which is related to the wave height. To get an accurate answer for higher waves the perturbation series must be taken to higher order, that is, more and more corrections are needed. Sir George Stokes found the third-order correction in 1847 (ref. 1) for periodic waves in water of arbitrary, uniform depth and the fifth-order, deep-water correction in 1880 (ref. 2). His results indicate that for low-but-finite-amplitude waves the speed of wave propagation (the phase speed) increases with the wave height. The fluid particles no longer move in closed orbits, but they acquire a small, added, down-wave drift called the Stokes drift. Also the wave profile does not remain symmetric about its mean level as in a small-amplitude sinusoidal wave, but instead the crests become higher and sharper and the troughs flatter. Unfortunately it is not possible to carry out the Stokes expansion to a high enough order by hand to accurately determine the properties of the highest wave because the amount of algebraic manipulation required increases dramatically with order. Indeed the tenth-order, deep-water correction was not obtained until 1914 (ref. 3), and the fifth-order, general-depth one was found in 1955 (ref. 4). Slow progress has also been made for solitary waves⁵⁻¹² with the third-order result being obtained in 1971 (ref. 12).

A separate and completely independent line of reasoning yields some information about the highest wave. In general at a wave crest the fluid particles are moving forward at a speed less than the phase speed (c), and as higher waves are considered the particle velocity approaches the phase speed. In a limiting wave these two velocities are equal. A further increase in wave height will cause the fluid particles to overtake the wave itself, and breaking will ensue. In the reference frame moving with the wave the water comes to rest at the crest, and it must attain a sharp point¹³ with an included angle of 120° as shown in Fig. 2. This corner-flow is only a first approximation valid very close to the crest and includes no information about the rest of the wave or about lower waves.

There have been several attempts to bridge the gap between the finite-amplitude theories and the highest wave. Some theoreticians have tried to build the 120° angle into the theories¹⁴⁻¹⁷, but it is not clear how this should be done¹⁸⁻²⁰. Many purely numerical approaches have been tried²¹⁻³⁰, and these are successful for small to moderately-high waves. They usually involve guessing the wave shape and then adjusting this until some error criterion is satisfied at a number of points along the wave profile. The advantage of these methods is that a high-

speed computer can be used to do the calculations, but often they fail to reach acceptable accuracy levels when the highest wave is approached.

Some recent advances have been made with perturbation expansion methods in which the laborious algebraic manipulations are carried out automatically by computer^{19,31-34}. The series can be expanded to a very high order (past order 100 in some cases) and summed efficiently thus providing accurate answers up to very near the highest wave. Stokes' original expansion procedure fails for high waves since his expansion parameter does not always increase with the wave height¹⁹; therefore two distinct waves exist for the same value of this parameter. The wave height itself can be used as an expansion parameter¹⁹, but its maximum value is not known beforehand. This difficulty is overcome by defining a new parameter (ϵ) in terms of the fluid speeds at the wave crest (q_{crest}) and trough (q_{trough}) in the moving reference frame³²⁻³⁴. The complete range of this parameter ($\epsilon^2 = 1 - q_{\text{crest}}^2 q_{\text{trough}}^2 / c^4$) is known from the beginning. For a small-amplitude wave the water streams past to the left at the phase speed ($q_{\text{crest}} = q_{\text{trough}} = c$, $\epsilon = 0$), and for a highest wave it comes to rest at the crest ($q_{\text{crest}} = 0$, $\epsilon = 1$). The wave height increases steadily with ϵ to values of $H/\lambda \approx 1/7$ for deep-water waves and $H/d \approx 5/6$ for solitary waves, but other wave properties behave in a surprising manner. The phase speed, momentum and energy increase with wave height initially, reach maxima, and then decrease as the highest wave is approached³²⁻³⁴. Therefore the highest wave is not the most energetic as had always been assumed. This behaviour is illustrated in Fig. 3 which is a typical plot of the kinetic energy of the wave against ϵ^2 for various ratios of water depth to wavelength³⁴.

The energy maxima can be explained in terms of the wave profile^{32,34,35}. At the crest the profile of the highest wave is above that of a slightly lower wave, but because of the sharp peak it falls away more rapidly and soon dips below the lower wave. Considered as an average over a wavelength, the highest wave is actually lower than an almost-highest wave; hence

Fig. 3 The average kinetic energy per unit surface area (T) of a steady wave plotted against the expansion parameter, $\epsilon^2 = 1 - q_{\text{crest}}^2 q_{\text{trough}}^2 / c^4$, for various water depths (d) (ref. 34). For each depth the highest wave corresponds to $\epsilon^2 = 1$. Notice that each curve reaches maximum energy for waves lower than the highest. Quantities are measured in units of density (ρ), wave-number ($k = 2\pi/\lambda$) and gravity (g).

Fig. 4 The four main breaker types: *a*, spilling; *b* plunging; *c*, collapsing, and *d*, surging.

it has less energy. These surprising results have been confirmed by separate numerical³⁵ and analytical³⁶ approaches which are completely independent of the perturbation series.

The existence of the maxima in the wave property curves may have a bearing on why high symmetric waves begin to break^{32,34}. Usually a wave is specified uniquely by the water depth, wavelength and one other wave property. But because the curves of these properties bend over for very high waves two distinct states are possible with the same wave energy, say, but with different wave heights. The solutions corresponding to one part of the curve may be unstable, and a wave might jump from one part to the other. Alternatively symmetric waves may become unsymmetric at the peak of their energy curves making the highest wave inaccessible except through the loss of energy. Other possibilities exist, and there is scope for further research in this area.

Several laboratory experiments have been carried out to test the validity of the steady wave theories. Usually low waves are generated in a long, narrow tank with a paddle, piston or wedge-shaped plunger and are sent into a channel with a sloping bottom or converging side walls to build up their height. In the test section simple measurements of the water depth, wave height and phase speed can be made. The measured phase speeds and limiting wave heights agree with theory to within experimental error (a few per cent), but the observations are not precise enough to detect the phase speed maxima³⁷⁻⁴¹. Indeed it is difficult to produce very-high waves which remain steady and do not break. Whether this is due to the method of wave generation or due to an inherent instability has yet to be determined. In more complex experiments the surface profile, velocity distribution, particle orbits and accelerations have been measured⁴¹⁻⁴⁵. Comparisons with low-order, finite-amplitude theories (Stokes' third order) in deep water are acceptable, but they worsen as H/λ and H/d increase. Differences of 50% between the theoretical and the measured (theoretical > measured) fluid velocities are common for $d/\lambda = 1/10$ and wave heights of about half the maximum. This is unacceptable for design purposes since the hydrodynamic drag on a structure varies as the square of the velocity so that a 50% velocity error produces a 100% drag error. The most widely used numerical method²³ does somewhat better, but it is inaccurate for high waves in all water depths³⁴. The discrepancy between theory and observation is probably due to the low order of the theories used. Their slow convergence rate for

shallow-water is well known^{1,2}, and it is quite likely that the inclusion of higher-order terms will bring about a marked improvement. The results of the recent high-order calculations^{19,31-34} have yet to be compared in detail with experiments.

Surface tension becomes increasingly important as the curvature of the wave crest increases, and this effect will be amplified in a small-scale laboratory experiment where the wavelength is 10^{-2} that of a typical ocean wave. Surface tension makes it impossible for the highest wave crest to attain a sharp point, and what this will do to the energy maxima is not known. Ripples are generated at the highly curved crest, and these ride along on the forward face of the wave^{46,47}. At present no high-order theories include both gravity and surface tension, but this is a future goal. An exact theory does exist for pure capillary waves in which surface tension provides the restoring force and gravity is neglected⁴⁸⁻⁴⁹, but owing to viscosity this is hardly, if ever, applicable.

During breaking

We now turn to the time-dependent behaviour of waves as they steepen and overturn. Roughly speaking a wave will tend to break when the local energy density (E) exceeds a critical value (E_{max}), that of the most energetic steady wave of the same wavelength and water depth. This happens during shoaling when the energy scale (E_{max}) decreases shoreward, and E/E_{max} increases until the break point.

Results from laboratory experiments with shoaling waves indicate that breakers can be classified into four main types⁵⁰⁻⁵⁵—spilling, plunging, collapsing and surging—as illustrated in Fig. 4. The breaker type depends upon both the initial wave energy, characterised by the offshore wave steepness (H_0/λ_0), and the rate of energy input due to shoaling, characterised by the beach slope (s) (refs 40, 52-54, 56). A breaker parameter (B) representing the ratio of these two effects can be defined by $B = H_0/(\lambda_0 s^2)$ (refs 53, 54). As B decreases from large values there is a progression from spilling to surging breakers. A spilling breaker which occurs when a steep wave approaches a gradually shoaling beach is similar in profile to a steep, symmetric wave, but it has a turbulent plume of frothy water running down its forward face (Fig. 5). Apart from this turbulent region the flow is irrotational. A value of B of approximately 5 marks the transition from spilling to plunging. In a plunging breaker the wave steepens and overturns ejecting a jet of water from near its crest which eventually strikes the surface below (Fig. 6). The flow may remain laminar (non-turbulent) until right up to the point of impact, or the jet may become turbulent due to the growth of small scale instabilities induced by the wind and surface tension. The third breaker type is the collapsing breaker in which the wave overturns not at its crest but lower down the forward face, and a region of white water

Fig. 5 A spilling breaker in shallow water (photo copyright Institute of Oceanographic Sciences).

Fig. 6 A plunging breaker in shallow water (photo copyright J. D. Humphery).

forms probably due to the close proximity of the bottom. This type is not as clearly defined as the others, and it denotes the transition between plunging and surging at $B \approx 0.1$. The surging breaker moves up a steep beach as the forward tip of a low wave. It resembles a standing wave formed by total reflection from a vertical wall, but a small amount of turbulence may be present at the beach face.

Two of the shallow-water breaker types—spilling (Fig. 7) and plunging—can occur in deep water. The bottom slope is no longer relevant since the bottom is far away and does not affect the dynamics. Deep-water waves can receive an input of energy when they overtake or collide with one another, meet an opposing current or receive a 'push' from the wind. In a laboratory wave tank the energy input can be provided by a converging side wall which acts in a way similar to a sloping beach. There is a transition from spilling to plunging as the initial wave steepness decreases and the channel convergence increases⁴¹. For gently spilling waves $H/\lambda \approx 1/7$ which confirms that a spilling breaker may be thought of as a just-breaking, highest, symmetric wave. Collapsing and surging breakers do not occur in deep water, but their counterparts are a mixture of progressive and standing waves. In the limit when two identical wave trains propagating in opposite directions collide there exist pure standing waves. The highest standing wave of periodically recurring permanent shape has $H/\lambda \approx 2/9$ (refs 57, 58). Not much is yet known about the breaking characteristics of standing waves or of mixed waves.

Experiments with breaking waves in shallow water have concentrated on how the ratio of wave height to water depth at the break point (H_b/d_b) and the ratio of breaking wave height to initial wave height (H_b/H_∞) vary with initial wave steepness and beach slope. Some empirical relationships based on scattered experimental data have been derived⁵⁹, but not a great deal of confidence can be placed in them. Generally for spilling breakers H_b/d_b is in the range 0.65–0.85 (refs 50, 52, 54, 60) which is approximately that value obtained from the highest solitary wave theory. For plunging breakers H_b/d_b increases, and values as large as 1.3 and 3.0 have been measured for periodic^{50,52} and solitary^{60,61} waves respectively, H_b/H_∞ equals about 1 for gently spilling waves which break almost immediately upon shoaling and increases to about 2 for plunging breakers^{50,52}. The behaviour as the ratio of wave steepness to beach slope tends to zero is not well defined. If the slope is small but finite and the initial wave steepness tends to zero an incoming wave splits up into a series of solitary-like waves (solitons) of different heights, and the highest breaks first as a spilling breaker⁵⁴. But if the initial wave slope is held fixed and the beach becomes a vertical wall (s_∞), an incoming wave will be totally reflected if low enough or break as a surging breaker.

A few measurements of the velocity distribution in spilling and plunging breakers have been made in the laboratory^{41,42,50,52,62,63} and the field⁶⁴. Generally with increasing profile asymmetry the rapid-forward-velocity region beneath the crest deepens, and the velocity vectors there become tilted upward as in accordance with the formation of a plunging jet. On sloping beaches the backwash of the previous wave augments the velocity asymmetry and helps to topple the wave^{50,52,64}. In the most precise experiment⁴¹ the crest velocity of a deep-water plunging breaker was 1.6 times the phase speed just after the onset of breaking.

No analytical theories adequately describe the time-dependent process of wave breaking. Theories exist for small-amplitude, shallow-water waves, but these are approximations valid only when the wave slopes are low or when the fluid acceleration is small compared with gravity^{65,66}. When the free surface steepens the fluid acceleration becomes comparable with gravity and cannot be neglected. An attempt has been made to study the effect of a small perturbation on the 120° corner-flow⁶⁷, but this theory is not appropriate since the solution contains undesirable mathematical singularities both before and after the instant of breaking.

Modern numerical techniques have had some success in describing breaking. The method most widely used by ocean engineers involves actually measuring the profile of a breaking wave and then fitting an irrotational flow to this by minimising the departure from constant atmospheric pressure along the surface²³. It has three major disadvantages: (1) the wave shape is assumed to be steady which is certainly not true during breaking, (2) the method cannot represent overturned waves, and (3) it cannot predict the evolution of a wave. It does give a rough estimate of the velocity field, and experimental comparisons indicate velocity errors of 10%–30% beneath spilling breakers at the break point⁶³.

A series of finite-difference numerical methods have been devised to deal with free-surface deformations. The two-dimensional fluid region is divided up into a number of small cells, and the velocity and pressure gradients are approximated by their differences across the cells. Marked fluid particles denote the free surface, and these are moved every time step by velocities interpolated from the cell boundaries. An early method⁶⁸ allowed the free surface to curl over, but an artificially large fluid viscosity had to be used to damp out unwanted 'wiggles' (numerical instability). A modified inviscid method⁶⁹ is more accurate and has been used successfully to calculate the run-up of a solitary wave on a steep beach. But it fails at the point of spilling when a solitary wave approaches a gradual beach because it cannot cope with an overturning surface⁷⁰. Similar methods which allow the cells to move with the fluid should do better, but available computer resources limit the minimum cell size so that the cells become too distorted for acceptable accuracy as the wave steepens⁷¹. Attempts to rezone the cells lead to instability at breaking⁷².

A different formulation has made it possible to follow waves as they overturn⁷³. One of the properties of irrotational flow theory is that the shape of the fluid boundary and the value of the velocity potential on that boundary uniquely determine the flow-field inside. Therefore only the evolution of the free surface need be considered, and all the computational effort can be focused there to accurately resolve its shape. At a given instant the tangential and normal velocities of the surface which are needed to follow its evolution can be found by numerical differentiation and by the solution of a linear integral equation. Initially computational particles are distributed on the free surface, and their trajectories are calculated in time steps⁷³. Figure 8a (Cokelet, unpublished work) is a computer-generated plot of the profile of a periodic, deep-water wave at various times as it steepens and overturns. The initial wave moving to the right begins as a sinusoid but with too much energy ($E = 5/3 E_{\max}$) to remain symmetric. Figure 8b illustrates a portion of the wave profile near the crest as seen by an observer moving at the speed of a small-amplitude wave. The profiles, plotted from

Fig. 7 A deep-water spilling breaker (or whitecap) moving toward the left (photo copyright J. R. Dunn).

the instant the wave face becomes vertical, show the crest toppling over towards the water below, but the theory does not remain valid past the point of impact. For spilling-like breakers the radius of curvature at the leading edge of the jet approaches the scale of the particle spacing, and the computations must be halted owing to numerical inaccuracies. Since irrotational flow is assumed there is no turbulent spilling, and the neglect of surface tension means no droplets pinch off. Numerical experiments are being conducted to determine how the plunging jet's momentum and energy depend on the initial conditions and energy input.

In some instances contrary to our simplifying assumption the airflow does have an effect on breaking. The wind creates a thin, sheared layer of water at the surface (the wind-drift layer), and this can augment the fluid particle velocity at a wave crest forcing the wave to break at a height below the maximum⁷⁴. Also the wind can blow-off or hold-up the wave crests, but this has not been studied. Conversely, breaking itself can influence the airflow, and this may help to explain how the wind makes waves. The airflow over a wave has a horizontally varying pressure field which must be shifted laterally with respect to the wave to feed energy into it⁷⁵. Theories which assume small-amplitude waves predict a wave growth rate which is much lower than that observed⁷⁵. But some new experimental findings show that breaking forces the airflow to separate from the wave surface thus shifting the pressure field so that it can do more work on the wave⁷⁶. Therefore wave growth is actually triggered by breaking which is a dissipative process.

After breaking

In shallow water after the period of rapid wave steepening and overturning there can exist a much less time-dependent period

in which the energy dissipated in the breaker approximately balances the increase of relative energy ($E/E_{\max}$) due to shoaling.

For a spilling breaker a turbulent, air-water mixture (a plume) runs down its forward face accelerated by gravity and retarded by the entrainment of up-slope momentum from the flow below. Theoretical considerations⁷⁷ based on the assumption of steady flow show that the plume can exist only if the surface slope and density difference between the whitecap and the water are sufficiently large. For a 30° surface slope corresponding to the 120° corner-flow, the plume must be about 8% air which is in agreement with observations of other self-aerated flows. The plume theory indicates that, once formed, a whitecap will tend to spread down the wave face, but energy balance considerations show that the ratio of whitecap length to wave height should be about constant⁷⁷. Since the wave height tends to diminish shoreward of the break point no true steady state can exist. It is observed^{55,77} that the whitecap grows, and its damping effect overcomes the effect of wave steepening due to shoaling. The wave crest becomes rounded which reduces the slope and allows part of the whitecap to be swept back over the crest. The wave then steepens, and the whole process repeats itself as long as sufficient wave energy remains⁷⁷.

After a wave has broken a step-like jump in the free surface can form and advance shoreward as a bore. Due to limitations of space we will not consider bores in detail but instead refer the reader to reviews on them⁷⁸ and on related hydraulic jumps⁷⁹. However, a recent numerical investigation which goes somewhat farther than previous ones should be pointed out⁸⁰. In this the run-up of a bore on a sloping beach is modelled. It is possible to follow the water up the beach until its forward tip gets very thin and then to follow its subsequent rush seaward (backwash) which itself develops into a bore. Preliminary results for a series of bores approaching periodically from the sea indicate that the maximum water velocity actually occurs during the backwash stage which may be of significance for sediment-transport studies.

Fig. 8 *a*, Computer-drawn profiles of a plunging breaker in deep water at successive time intervals of about $1/25$ of a wave period ($\Delta t = 1/4$ in units of p, k and g). The initial wave form is sinusoidal with its crest at $x = \pi/2$, but it has too much energy ($E = 5/3 E_{F_{\max}}$) to remain symmetric. Therefore the wave steepens and overturns. *b*, A portion of the crest plotted about every $1/50$ of a wave period ($\Delta t = 1/8$) as seen by an observer moving to the right with the speed of a small-amplitude wave ($c^2 = g/k$). The profiles are plotted from when the wave face becomes vertical, and the dots mark the computational particles (Cokelet, unpublished work).

For a tsunami the ratio of offshore wave steepness to beach slope is very small, and the wave usually does not break at all. In that case the maximum shoreward excursion of the water (the run-up distance) is of particular interest to those concerned with tsunami prediction and the design of shoreline structures. Advances have been made in the theory of wave run-up, but it is beyond the scope of this paper to consider them here (see ref. 81 for more details).

Conclusion

We understand some things about breaking waves especially before and after breaking when the flow is steady and more amenable to theoretical and experimental study. But there are large gaps in our knowledge. Much has yet to be learned about the time-dependent period during breaking. Laboratory experiments performed in shallow water have provided some information about this, and numerical investigations are likely to prove fruitful in the future. In this exciting field many questions remain unanswered. What are the velocity and acceleration fields in a breaking wave? How much of its momentum and energy are given up to ocean currents and turbulence? What is the spatial distribution and frequency of breaking? There is great potential for further theoretical and experimental research. The spectacular fury of a breaking wave stimulates the search.

Acoustic oceanography

Walter H. Munk & Gordon O. Williams

Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093

Measurements of ocean finestructure (with typical time scales of 15 min to 1 d, spacial scales of 10 to 100 m vertically and 1 to 10 km horizontally) are consistent with the measured variability in the transmission of acoustic signals through the ocean volume. The observations suggest that the statistics of acoustic fluctuations can be used to monitor the statistics of ocean finestructure. Further, fluctuations in the travel time are a measure largely of temperature fluctuations along the acoustic path, and the difference in reciprocal travel times is a measure of the component, along the path, of current and current shear. Such acoustic measurements give integrals along the paths, with the attendant advantages and disadvantages as compared with the traditional 'spot' measurements; precision promises to be comparable or better.

OCEANOGRAPHERS differentiate between marine biology and biological oceanography. The former is concerned with biological processes in marine organisms; the latter places emphasis on biological processes in interaction with physical, chemical and geological processes. Biological measurements can serve as sensitive indicators of the source of water masses, of vertical motion and mixing processes, etc. It is in this sense that we distinguish acoustic oceanography from the intensively active field of marine acoustics.

During and directly following World War II, the interaction between the acoustic and oceanographic communities was close, to the benefit of both. Certain noises in the oceans could be traced to biologic origin, such as snapping shrimp. The deep scattering layer was discovered and readily associated with the known diurnal migration of copepods, towards shallow depths at dusk and downward at daybreak. (Details concerning the organisms among the migrating biomass that provide the

Fig. 1 Phasor diagram of acoustic transmission. The curve consists of straight-line segments through points at 5-min intervals. The distance of a point from the origin (not plotted) is proportional to the intensity, and its bearing angle to the phase of the received signal relative to that at the transmitter. The random walk character of the phasor diagram is associated with interference between many multipaths. The plot was made by computer simulation of the MIMI experimental conditions.

acoustic scattering cross section are complex and not totally solved even today.) The 'afternoon effect' of sharply reduced sonar ranges was explained quantitatively in terms of radiative warming of the near-surface waters. The existence of an acoustic wave guide (the SOFAR channel) was proposed on the basis of the known interior distribution of temperature and pressure, and dramatically demonstrated soon thereafter.

It was then generally accepted (primarily because the oceans are so transparent to sound and opaque to light) that sound propagation would develop into a primary tool for probing and monitoring the oceans. But by and large, the close cooperation between oceanographers and acousticians did not continue. We think this might have to do with the fact that the acoustic community became strongly concerned with the large variability in sound propagation; 20 dB fades are by no means uncommon. And here the oceanographic community was of no help. Oceanographers were preoccupied with very large scale, long time processes, d.c. oceanography so to say, that have little bearing on acoustic variability. What was needed here was a description of the ocean structure on a small scale, and the instruments for making the required measurements had not been developed.

And so the two communities went their own ways, to the detriment of both. The oceanographers were so preoccupied with their wind-spun oceans that they neglected the mesoscale and small-scale processes which contain (as we now know) 99% of the kinetic energy. The acousticians invented their own oceans, borrowing the concept of a homogeneous isotropic turbulence which had served as a successful model for explaining the fading of radio waves in the ionosphere. Temporal fluctuations were interpreted in terms of a frozen ocean structure drifting by (Taylor's hypothesis). But the ocean is neither homogeneous nor isotropic (except possibly on scales less than 1 m. Further, Taylor's hypothesis supposes that the mean currents (winds) exceed the intrinsic velocities of the structure. But in the oceans, the phase velocity of internal waves, for example, is typically 1 m s^{-1} , and the mean motion typically

0.1 m s^{-1} . So there is no justification for Taylor's hypothesis, yet it remains ingrained in the acoustic literature (A. W. Ellinor has pointed out to us that most of the existing acoustic observations were carried out from moving vessels, and then the application of Taylor's hypothesis is entirely justified.)

In the 1950s it became apparent that discrepancies between successive measurements at repeatedly occupied oceanographic stations were not always the result of instrumental error. Since then, the development has been rapid. Ocean eddies with time-scales of several months and space scales of 100 km were found to be associated with 100 times the kinetic energy of the general circulation. At frequencies between a few cycles per hour (the Brunt-Väisälä frequency) and a cycle per pendulum day (the inertial frequency) internal waves dominate. Their vertical amplitude is remarkably large, 10 m in the upper oceans, up to 100 m at abyssal depths. The time was ripe to inquire whether internal waves could account for some of the measured variability in the propagation of sound through the ocean.

A long-range sound transmission experiment

In 1966 Steinberg and Birdsall conducted a pioneering sound transmission experiment across the Straits of Florida¹. Interpretation was made difficult by shallow-water effects, and subsequent efforts were shifted to a 1,250 km path from Eleuthera to Bermuda². An essential feature in these experiments (called MIMI for the Miami-Michigan participation) was that they gave continuous observations over many months, and this opened the way for a geophysical interpretation. In essence, the experiment consisted of transmitting a 406-Hz continuous wave signal, and of recording the relative phase and intensity of the received signal using a perfectly synchronised 406-Hz oscillator. The resulting time series of acoustic phase and intensity are dominated by occasional fade-outs and phase jumps which are the result of interference between the many paths from source to receiver (Fig. 1). This is an interesting problem in random-walk statistics, but unfortunately the ocean is involved only in a limited way: the determination of a single parameter, $\langle \phi_1^2 \rangle$, the mean-square rate of phase along any one single path (Fig. 2) (ref. 3). The parameter could in principle be measured directly if such a single path could be isolated from all other paths by a suitable directional antenna. But this is not possible, because each 'deterministic' path is split into 'micro-multipaths' (Fig. 3).

Fig. 2 Phasor diagrams for single path (a) and multipath (b) acoustic transmissions. The Cartesian coordinates designate the in-phase and quadrature components of the received pressure signal, at time 1, 2, ..., with the vector indicating the positions at time 1. ϕ_1 and $I_1 = 10 \log(x_1^2 + y_1^2)$ are the single path phase and dB intensities, and similar ϕ and I for the multipaths. Generally $\theta(t)$ varies more rapidly than $\phi_1(t)$, and $I(t)$ is more variable than $I_1(t)$. Passage of the vector trajectory near the origin (between times 5 and 6 in the right figure) is associated with a fade-out and a rapid change of phase by almost $\pm 180^\circ$, the sign depending on which side of the origin is passed (minus in the figure).

Fig. 3 According to the Dashen systematics, the character of acoustic transmission depends on the region in the Λ, Φ -diagram; Λ depends on the scale and Φ on the strength of the fluctuations in sound velocity. The Λ, Φ -parameters associated with various transmission experiments are shown. The functional dependence of the dimensionless coordinates on range R and frequency σ are indicated. For orientation, numerical values of R and σ are given for the special case of an upper path, and for scatter by a model ocean and model internal wave spectrum. (Accordingly, the actual Azores range of 35 km is inconsistent with the R -contours.)

What is measured is the vector sum of all paths, giving the intensity $I(t)$ and phase $\phi(t)$ of the combined multipath signal. The multipath $\langle \phi^2 \rangle$ is not the same thing as the singlepath $\langle \phi_1^2 \rangle$; it is generally larger and shows occasional near-180° 'jumps' associated with intensity fadeouts. Over a period of a month ϕ can change by many cycles, and it is necessary to keep track of the sign of the phase jumps. $\langle \phi^2 \rangle$ increases linearly with record time in accordance with random-walk statistics. (If one can measure travel time—for instance by measuring the group delay between two frequencies, or with broad band pulses—then the phase locus through the fade loses its stochastic property (personal communication from A. Ellinthorpe and T. Birdsall).) The spectrum of $\phi(t)$ contains high frequencies (associated with phase jumps) and low frequencies (associated with random walk) that are not contained in $\phi_1(t)$.

Even though the singlepath $\phi_1(t)$ is not directly measured, it can be inferred from the multipath statistics under quite reasonable assumptions³. The result is

$$\text{r.m.s. } \dot{\phi}_1 = 2.8 \times 10^{-3} \text{ s}^{-1}, 4.0 \times 10^{-3} \text{ s}^{-1} \quad (1)$$

for Mid-Station and Bermuda, respectively.

This parameter depends on the fluctuations of sound velocity along the transmission path, and can be calculated if certain statistical properties of these fluctuations are known. A statistical model of internal waves has been produced by Garrett and Munk⁴ from various oceanographic measurements (see ref. 5). An unexpected result was a high degree of universality with regard to time and place of observations, except perhaps in the close proximity of seamounts and other potential sources⁶. Internal wave motion dominates in the frequency band from cycles per hour to cycles per day. Munk and Zachariasen⁷ have computed the fluctuations in sound transmission for this particular model of ocean finestructure, and obtained

$$\langle \dot{\phi}_1^2 \rangle = 8\pi^{-2} \langle (\delta C/C)_{\text{axis}}^2 \rangle q^2 B R \omega_{in} n_0 \ln(n_{\text{axis}}/\omega_{in}) \langle j^{-1} \rangle \quad (2)$$

for the mean-square acoustic phase variations along an axial ray. Here n_0 and n_{axis} are values of the buoyancy frequency at the surface and sound axis, $\delta C/C$ is the sound velocity perturbation due to internal waves, q is acoustic wavenumber, B the scale depth of stratification ($dn/dz = -z/B$), R is range, ω_{in} is inertial frequency, and j is the internal wave mode number. An internal-wave-weighted average of j^{-1} equals $\langle j^{-1} \rangle = 0.44$. Equation (1) leads to the result

$$\text{r.m.s. } \dot{\phi}_1 = 3.5 \times 10^{-3} \text{ s}^{-1}, 5.2 \times 10^{-3} \text{ s}^{-1} \quad (3)$$

for the two stations. There are no loose parameters here, and the datasets underlying (1) and (3) are entirely independent, one acoustic, the other oceanographic. We would conclude that a connection has been made between the acoustician's ocean and the oceanographer's ocean. (A more detailed analysis allowing for non-axial ray paths leads to a somewhat lesser agreement.)

An interesting remaining question is whether the low-frequency $\phi(t)$ variations can be entirely ascribed to random-walk statistics, or whether they are in part the result of low-frequency ocean variations, such as mesoscale eddies.

Transmission over Cobb Seamount

Ewart⁸ transmitted 4 and 8 kHz pulses for about a week between source and receiver placed on Cobb Seamount at 1 km depth and 17 km separation. Ray-tracing gives a single downward refracted path with a turning point at 1,350 m. With this single-path geometry one can attempt to interpret the entire measured spectra of phase and intensity with those derived from an ocean model. Accordingly, much more can be learned than from the single parameter $\langle \phi^2 \rangle$ in a multipath experiment, at the expense, of course, of monitoring a much smaller ocean volume.

From the internal wave model one computes a phase spectrum bounded by the inertial and buoyancy frequencies, and proportional to ω^{-3} at intermediate frequencies^{7,9}. The measured phase spectrum has some of these characteristics. The measured r.m.s.

Fig. 4 Sound speed as a function of depth and associated refracted ray paths. A surface duct path is also shown (from ref. 16).

(ϕ) is 1.6 cycles, the value computed from the ocean model is 0.8 cycles. Again there are no loose parameters. But, the measured intensity fluctuations greatly exceed the computed fluctuations, particularly at high frequencies. The discrepancy has not been explained. It could be the result of ocean finestructure over the seamount which differs from typical open ocean conditions, although environmental measurements did not indicate a marked difference.

Acoustic experiment in the Azores

Ellinthorpe's¹⁰⁻¹² ambitious transmission study AFAR in the Azores involved a source at 550 m depth and a receiver at 750 m depth separated by 35 km. The refracted ray is limited by the source depth above, and the sound velocity maximum associated with the Mediterranean outflow at 800 m below. The experiment was conducted over a broad range of acoustic frequencies, and involved an intense program of ocean monitoring.

Interpretation of Ellinthorpe's experiment has gone well beyond the analysis of variance. For this purpose we need to refer to systematics developed by Dashen¹³. According to this systematics the signal statistics fall into five distinct classes, depending on the values of two parameters (Fig. 3). The diffraction parameter $\Lambda = (2\pi)^{-1} R_F^2 / L_V^2$ depends on the Fresnel radius R_F and the vertical coherence scale L_V , of the inhomogeneities. The strength parameter $\Phi^2 = \langle [q \int (\delta C/C) ds]^2 \rangle$ depends on the perturbations in sound velocity integrated along the ray path, with q designating acoustic wavenumber. In the lower region of Fig. 3, simple geometric optics and the Rytov extension apply. Ray paths undulate, but they are not split into micro-multipaths. Accordingly, the transmission time of an acoustic pulse will wander, but the pulse shape remains essentially undistorted. In the upper region the deterministic ray path is split into incoherent micro-multipaths, a transmitted pulse is severely distorted and spread, and C.W. intensity fluctuations are saturated in consequence of interference between these paths.

The Azores experiment is in an intermediate region where the intensity is only partially saturated. This, as with other inferences,

Fig. 5 Arrival amplitudes at 30-s intervals after high resolution processing (from ref. 16). Time is relative to the start of the transmitted pulse. Note the internal wave-caused relative complexity of the later, upper path arrival.

is in rather remarkable agreement with observations¹³, and give support to the hypothesis that the fluctuations are the result of internal waves. But most of the first-order statistics do not distinguish sensitively between an internal wave model and the Taylor hypothesis that the inhomogeneities are convected. But, some second-order statistics, such as the intensity covariance, are sensitive to this assumption, and the results are inconsistent with the Taylor hypothesis and consistent with an internal wave model¹³.

An experiment off California

We are preparing for a joint experiment¹⁴ to explore further the transition from unsaturated to saturated forward scattering. We will use multiple moored sources and receivers 250 nm offshore from southern California under a simple ocean geometry, that is, deep water and no seamounts. The moorings will be submerged and self-contained; the penalties for this relatively simple arrangement are the need for Rubidium clocks at each mooring and the need to monitor the mooring motions.

In terms of Dashen's systematics (Fig. 3), the planned diversity of frequencies (220 and 2,250 Hz), ranges (25–125 km), and paths (upper and lower) will cover the transition from geometric optics to coherent micro-multipath (2,250 Hz, SIO) and the transition from geometric optics to incoherent micro-multipath (220 Hz, WHOI). Associated ship-based listening stations will extend the 2,250 Hz observations to the incoherent micro-multipath regime. The experiment should provide a crucial test as to whether internal waves impose the fundamental coherence limits (space and time) to marine acoustics.

A second (and related) goal of this work is to assess the role of acoustic oceanography in synoptic monitoring of the oceans on a mesoscale (~ 100 km). It has become increasingly apparent in the last several years that most of the kinetic energy of the oceans is contained in mesoscale processes¹⁵. Mesoscale 'eddies' are analogous to atmospheric storm systems ($\sim 1,000$ km scale). This disparity in spacial scales makes the preparation of an 'ocean weather map' more difficult than preparation of the corresponding atmospheric map. A reverse disparity in time scales of ocean and atmospheric weather (~ 60 d compared with ~ 3 d) does not offset this difficulty. Acoustic oceanographic methods offer one possible mean for gathering data needed to map ocean weather.

The 2,250-Hz work off California is a preliminary step towards acoustic ocean monitoring. We will take advantage of the fact that the mean sound velocity profile gives one direct upper ray path and one direct lower ray path between two points located at about 1,000 m depth 25 km apart (Fig. 4). Travel time for reflected paths are well separated in time from those for direct paths and can easily be discriminated against. Very encouraging results from ship-based transmissions using this geometry (Fig. 5) have been obtained by Worcester¹⁶.

Changes in the oceanographic variables—temperature, salinity, and current—contribute to changes in travel time. Simultaneous transmission of pulses in opposite directions differentiates between current effects and those of temperature and salinity. Worcester has attained an absolute travel time precision of 10^{-4} s and a relative precision of 2×10^{-6} s, using modified matched filtering techniques. A fluctuation in travel time by 10^{-4} s corresponds to a temperature fluctuation of 10^{-2} °C, a salinity fluctuation of 10^{-2} ‰ or a current of 1 cm s⁻¹ integrated along the ray path. The 25 km averaging accomplished by the adopted mooring spacing is appropriate for detecting structures of eddy dimensions. We would, therefore, expect a distinctive travel time signature from the drift of a mesoscale eddy past the moorings. Identification of the contribution of individual variables to the overall travel time effect is as yet unsolved. A complete solution of this inverse problem probably requires data from many ray paths, each giving the result of its own vertically and horizontally weighted mean.

An environmental measurement program will accompany the acoustic work to compare results of the acoustic measurements

with data from traditional oceanographic instruments. A measure of the degree to which acoustic monitoring fills an unoccupied niche is the difficulty one faces in using conventional instruments to 'check' acoustically derived data. Even for our small, two-mooring experiment, we have not found it practical to monitor both acoustic paths with moored instruments. We will instead use conventional current and temperature meters to make continuous measurements along the simpler lower ray path only. Frequent upper path measurements will be made with instruments lowered from ships. Comparison of acoustic and 'spot' measurements will be limited largely to subinertial and tidal frequencies.

Acoustic monitoring of ocean weather has an advantage over conventional methods: by measuring between stations rather than at stations the information collected goes up with station number like $n(n-1)$ rather than n (allowing for reciprocals). There are no major technological problems. Indeed, for these subinertial frequencies one would dispense with the bothersome mooring position-keeping. Surface floats could allow for radio

control of clocks. The automated analysis of acoustic signals is a formidable task, but existing microprocessor technology is adequate. Experiments over the next few years will go far towards determining the feasibility of 'listening' to undersea weather.

The life of the open sea

John D. Isaacs

Scripps Institution of Oceanography, Institute of Marine Resources, University of California, La Jolla, California 92093

"Third Fisherman—Master, I marvel how the fishes live in the sea.

First Fisherman—Why, as men do a-land; the great ones eat the little ones."

Pericles

THE living creatures of the near-surface waters of the open sea survive in one of the highly demanding and unforgiving habitats of the planet. Yet here a great and varied assemblage of creatures has evolved in or adapted into a vast realm that offers neither refuge nor obvious environmental niches to its myriad of inhabitants. The student of this region is strongly challenged by the very subtlety and obscurity of the adaptations and modes of existence, and often is astonished by his findings.

I will briefly review here some major aspects in the present understanding of the open sea, the nature of the forces and conditions that have set the range and compass of its progeny and will attempt to point out the curious and poorly understood steps that allow a relatively large population of highly developed, highly active animals to ensue from a food web initiated by microscopic plant cells, thinly dispersed in a dense fluid medium. I will speculate on defects in our present approaches towards understanding marine trophic (food web) systems and on an example of overlooked possibilities. Within the discussion, I will touch only briefly on adjacent interrelationships, coastal waters, shallow seas, coral shoals, and the environments of the deeper bathypelagic and benthic life. This short shrift to the boundaries of the environment that I discuss should be taken as a measure of the limitations of space rather than of importance, for the children of Tethys and the flocks of Nereus are, of course, no more isolated from the conditions and inhabitants of other realms than the disciplines of modern marine science can be cleaved one from another.

A properly structured discussion of any living system will begin with the processes by which the inorganic chemical and energetic sources enter and recycle in the system; and proceed with the living autotrophic entities that catalyse the elaboration of initial organic material from these lifeless sources. It will then describe the myriad and often

bizarre living forms and trace the Byzantine paths by which this organic material is utilised for its substance, processed for its energy, and finally returned again to the inorganic reservoir. I point out some developments that modify the classical visualisation of these steps.

Modern research largely affirms the broad aspects of the conventional concepts of the initial input of inorganic nutrients into the near-surface waters of the ocean. In this picture the special chemical requirements of phytoplankton as well as those common to almost all plant life are abundantly supplied only in those parts of the sea where some dynamic process provides the mechanical work required to recycle nutrient-rich water from deeper levels where they have been released, into the lighted upper layers where they are used. But, these sunny well-ploughed pastures of the sea, where luminous and chemical needs coincide, account for only a few per cent of the ocean's primary productivity, for they are of limited area. They exist mainly along eastern boundary currents, in the Antarctic, and at the equator, where the processes of upwelling hold sway. Because of the vast extent it is the great oceanic areas that account for most of the total productivity some 80%, despite the low production rates in these leaner waters¹.

It is clear, however, that the classical picture of the primary trophic inorganic steps needs to be modified in detail. Certain algal colonies (blue-greens) elaborate significant quantities of the essential nutrient, inorganic chemically-bound nitrogen². The recycling of nutrients within shallow seas and shelves, in coral atolls and other environments apparently contributes more to their productivity than previously supposed. In such environments, there may be only very low levels of plant nutrients dissolved in the water, for here recycling and uptake proceeds apace³, as in jungle soil. Recycling may also be internal, within animal tissues that bear captive plant symbionts, as in the case of corals and the *Tridacna* (giant) clams⁴. Hence classical chemical measurements of dissolved nutrient levels and inferences of productivity may be wholly misleading. Another process that modifies the classical portrayal seems to take place in the very clear waters of central oceanic gyres. Here in the uppermost

levels of the thermocline is a layer dense in chlorophyll, although the light level of less than 1% of surface illumination is below the minimum previously assumed necessary for net phytoplankton growth⁵. Apparently excess chlorophyll along with ancillary pigments or other adaptations allow phytoplankters to grow at the poorly illuminated diffusing upper edge of the nutrient-rich submerged waters—a process probably only general in the relatively steady conditions and clear near-surface waters of central oceanic regions.

Thus in the light of modern research, the general elements of the classical portrayal of the first step of the trophic system, primary productivity, survive quite well. Subsequent aspects of the conventional food-web picture seem to require more modification, however.

For example, dissolved organic material (DOM, the 'gelbstoff', refractory highly oxydised organic substances of high molecular weight) may assume an increasingly important trophic role. This material is undoubtedly the greatest of the organic reservoirs within the ocean, 200 times the total phytoplankton and particulate organic material⁶. Furthermore, its average age (3,400 yr) (ref. 7) argues that it is only utilised or removed slowly and perhaps only in some special conditions. Slow recycling of this great reservoir may be conducted by certain recently isolated bacteria of deep water which can utilise it⁸. It may become rapidly available along the hydrothermal areas of deep rift zones at oceanic ridges, where heat, pressure, and brief reducing conditions may transform it into more available chemical forms. Wherever it is that DOM is recycled, food input could be very large. For example, the rate at which DOM becomes available in the North Pacific could exceed the primary productivity there by a factor of 10 (ref. 9).

Other modifications of the trophic picture emerge apace, and I will sketch only a few. Remarkable discoveries of the nature of metabolites and organic pathways include the demonstration of a bewildering range of halogenated organic products (a chemical province recently thought to be the chemists' exclusive domain) elaborated by marine plants for various defensive, offensive, and possibly communicative purposes¹⁰; the dominant role of waxes in major parts of the food webs of the open sea and coral reefs¹¹; the role of the ubiquitous behaviour of the active pelagic zooplankton and small nectonic (more strongly swimming) organisms in performing a diurnal round-trip migration from the surface to mid-depth, thus providing a number of functions—including leading them to productive areas¹²; the demands of energetics that force large active predators preferentially to select surprisingly small organisms for their major food resource¹³; the well-nigh invisible environmental niches provided for apparently fully equivalent species by their different responses—not to conditions—but to the time rate of change of conditions¹⁴; the remarkable chemotactic-motor trail-following behaviour of some marine organisms¹⁵; and many others.

In this last example, sergestid shrimp have been shown to follow a fine thread-like trail of amino acids with ultimate swimming speed and preciseness, an astonishing display of chemotactic motor control.

These examples epitomise the surprising discoveries that the observation of the forms, behaviour, and processes of life of the sea will ever yield up to its students. At the same time the same examples may also indirectly point to one of the deficiencies of the underlying observational, scientific, and philosophical approach to the trophic pathways of the open sea and perhaps to other aspects of marine biology as well.

The careful and thoughtful observations and measurements of living forms, behaviour and pathways have taught much important understanding in forest and grassland¹⁶ and in some estuarine, near-shore and other

environments. Yet in the open sea, and despite the inherent fascination of naturalists towards the activities of the creatures of the sea, many of the dominant activities and pathways are fundamentally not discernible. Major pathways of detritus, reproductive products, growth and dissolved organic material are virtually invisible, yet the delusion commonly persists that with only sufficient collections, observations, measurements and analysis, the full dynamic nature of the food webs of the open sea eventually will stand revealed. I will enlarge briefly on this, for it may well be the principal diastema in our philosophical approach to the trophic systems that dominate two-thirds of this planet.

The flow of food from initial microscopic levels of the open sea to higher forms such as fishes, squid, and marine mammals seems to be dominated by quite a different process from similar fluxes on land or near-shore and shallow aquatic environments, where the principal inputs are by large plants¹⁷. In the pelagic realm a sort of food web composed of the progeny of many species seems to constitute a major pathway of material to the larger forms. This pathway is dominated by growing larvae and juveniles, which suffer immense mortality in their role. It is a sort of huge polyspecific extension and exacerbation of the 'Faginism' observed in some cases. For example, in lakes that have been stocked with one species of predacious fish, a food web develops from successive predation of juveniles by larger juveniles ultimately supporting a few reproducing adults. Such a system is in sharp contrast with other food webs where large plants provide the initial input, large herbivores are supported, the populations are dominated by adults, and mortality is low.

Undoubtedly this system has developed in the open sea for access of the larvae and juveniles to the abundant microscopic and near microscopic food at the commencement of the food web. It is responsible for the immense flow of food material as reproductive products (egg, sperm, and larvae) from the higher forms down towards the beginnings of the system, and may be largely responsible for the very existence of higher forms in the open sea.

It is interesting to speculate on the role of those marine creatures that take from but do not contribute to these essential pathways. The terrestrial expatriates (marine mammals, birds and reptiles) and some sharks which bear large young, depend entirely on the peculiar pathways of the pelagic food web but escape from both the associated contribution to and the predation within the system upon which they are dependent. Any substantial dominance of these forms may thus lead to collapse of the entire higher pelagic system. This fundamental instability of the higher levels of the pelagic food web may illuminate events in the palaeontological record where explosive proliferation of highly-developed (and apparently viviparous) pelagic predators culminated in their own universal mass extinctions and that of many other higher pelagic creatures¹⁸.

The present marine mammals and tuna-porpoise policies need to be restudied in light of this possibly fundamental long term ecological instability of the pelagic system.

I will conclude with an added example of each of two principal themes on our understanding the conduct of living system of the open sea, one philosophical and one observational.

First, there are opportunities to view trophic systems by overleaping the details of processes with the same philosophy that enables us to coalesce a microcosm of molecular kinetic complexity into a single meaningful measure—temperature. Such an approach complements the more detailed naturalistic descriptions and measurements. One such model views organisms as operators that continually distribute and redistribute resources into a few specific reservoirs by appropriate transfer coefficients¹⁹. These reservoirs are, most simply, living material, dead

retrievable material, dead irretrievable matter, and reproductive products. The approach generates useful and meaningful expressions of potential relative biomass of trophic types and other trophic relationships, and seems to explain a number of anomalies, such as the frequent observation that the biomass of predacious forms exceeds that of the herbivorous forms with which they are in an apparent equilibrium. It also provides reasons for both the general immunity of marine organisms from the bioaccumulation of trace substances in the food web (including pollutants); and the vulnerability of marine birds and mammals to the bioaccumulative process.

As a final speculative example, aggregation of the active creatures of the open sea, such as schooling, is an almost universal feeding, defensive, predatory, or mating strategy. Indeed, the existence of both baleen whales and marine fisheries is almost wholly dependent on species that display strong schooling behaviour. Nowhere is schooling more conspicuous than in the small filter feeding fishes, the clupeoid sardines, anchovies, herrings and their relatives. It has long been known that schools of such fish are strong scatterers of underwater sound and easily detected by sonar devices. The strong sonar reflection of these fish is due to the abrupt discontinuity in sound velocity at the boundaries of their gas-filled swim bladders. Although underwater sound of the frequency and wave length in 'fish-finders' responds to the presence of a swim bladder as though it were a discontinuity in the water, lower frequency sound will respond to the swim bladder as a property of the medium. This is quite properly analogous to the scattering of light by fog and the penetration of such obscuration by radar.

Thus, 1,000-cycle (1 kHz) underwater sound with a wave length of almost 2 m will envelope a number of fish in the school per wave length. Simple calculations show that the velocity of low-frequency sound within a fish school can be as low as one-third the velocity in sea water. Such a change in sound velocity is orders of magnitude greater than that engendered by variations in the ordinary physical-chemical conditions of temperature, salinity, and

pressure. Thus to low frequency sound the fish school is a wholly unique object, and such sound must focus abruptly within the schools. A consequence of the schooling of small fish is thus the creation of an immensely powerful, complex and continuously pliant lens for the focusing of low frequency sound, a lens that is composed entirely of detectors of such energy! Here is an example of the development of certain qualities (for example, a hydrostatic device) and particular behaviour (for example, schooling) under quite disparate requirements interacting to form a wholly new advantageous property, which could not be approached at the level of mutation of the individual organism. In this case the serendipity is the creation of a unique living lens to magnify and respond to the sounds of distant predators!

In this brief resume of the life of the open sea, I have suggested some of the modifications of the classical picture emerging from the observations and the burgeoning new insights into its forms and processes; and some of the major deficiencies in the present approaches and philosophy.

I have also speculated on examples of the possible future advancements of understanding that the instructor, Nature, may ultimately teach us within the reaches of the great realm that encompasses two-thirds of the surface of this planet, the open sea.

Diversity and faunal composition of the deep-sea benthos

Torben Wolff

Zoological Museum, University of Copenhagen, Denmark

Improved techniques have demonstrated a remarkably high species diversity in the deep sea. Long-term environmental stability has resulted in establishment of diverse communities whose species have become biologically accommodated to each other. The deep-sea meiofauna (about 60–500 µm) mainly consists of foraminiferans and nematodes. The macrofauna is dominated by polychaetes, peracarid crustaceans, and bivalves. The major components of the megafauna are brittle stars bathyally, large scavenging fish and amphipods abyssally, and amphipods hadally. Biomass and numerical density decrease rapidly with distance from land. Biomass seems to be of the same order of magnitude for the three size groups, while meiofaunal density in the upper bathyal zone may be up to 1,400 individuals per 10 cm² and macrofaunal density 20,000 individuals per m².

In the last decade, modern techniques have led to many remarkable discoveries regarding life and life conditions in the deep sea. Rather than attempt a general brief survey of new knowledge gained in almost all fields of deep-sea biology, I have preferred to concentrate on a limited number of topics which represent some of the most striking advances in our conception of deep-sea life.

Species diversity

Until the 1960s it was the general experience that with increasing depth and distance from land the benthic fauna consisted of fewer individuals belonging to fewer species. The recent introduction in deep-sea research of the anchor dredge¹, the epibenthic sled², and careful washing of the samples through fine-meshed sieves drastically changed this concept. Greatly increased numbers of individuals now became available, numerically increasing the number of species, and also allowing the taxonomists to recognise that the samples contained numerous closely related species.

The high species diversity was first demonstrated in the

Fig. 1 Range for diversity values found for three shallow-water and two combined deep-sea environments (the latter in the NW and the SW Atlantic, 300–2,500 m). The figures in the bands indicate number of samples. (Slightly modified from ref. 6.)

north-western Atlantic². Samples subsequently taken off western Europe, in four basins off West Africa and in the Brazil Basin, collected and processed with similar methods, show the same general pattern.

For instance, three sled samples from the north-western Atlantic from 1,400, 2,900 and 4,700 m contained 25,200, 12,100 and 3,700 individuals belonging to 365, 310 and 196 species, respectively². The hitherto most successful deep-sea sample was taken with a large trawl in the East Pacific at 3,600 m and contained 2,100 individuals belonging to 132 species³. Among the dominant groups, the greatest diversity is invariably found in peracarid crustaceans, followed by polychaetes and bivalves, while ophiuroids are always represented by few species. If there is one species of brittle stars per 1,000 individuals, there are four species of bivalves, 10 of polychaetes, and 17 of peracarid crustaceans⁴. Also harpacticoid copepods, an important component of the deep-sea meiobenthos, show high diversity⁵.

In order to compare deep-sea diversity with that in shallow water, soft-bottom samples were obtained from, among other places, a boreal and a tropical estuary and a boreal and a tropical marine environment, and processed with the same techniques. Based on the polychaete–bivalve fraction of the fauna, which accounts for about 80% of the total fauna in most infaunal samples, and using a rarefaction methodology which allows direct comparison of samples with differing numbers of specimens, Sanders^{6,7} showed that only in the physically stable, shallow, tropical marine environment was there a diversity as high as that of the deep sea (Fig. 1). Conversely, a low diversity is characteristic in environments where physical parameters (for example temperature or salinity) fluctuate greatly.

Basic to Sanders' stability–time hypothesis is the idea that long-term environmental stability has allowed a highly refined competitive niche differentiation. Since food is the

most important limiting factor in the deep sea, each species may have evolved a high food specialisation, thereby avoiding competitive overlap with other species of the community.

Although they do not deny the presence of niche specialisation, Dayton and Hessler⁸ believe that continuous and intense biological disturbance by predators is the main element responsible for controlling population size and maintaining high diversity. They find that in the deep sea a high degree of food-niche specialisation is unlikely. There can be no sharp demarcation between deposit feeders and predators, because in order to survive, both categories must possess a certain flexibility in their food choice. An appropriate term for animals of such a broad feeding-type is 'croppers', that is animals of any size which consume live food, either alone or in combination with dead or inorganic materials. The pressure exerted by croppers on populations of smaller animals reduces the probability of competitive exclusion of the latter and allows a high overlap in the utilisation of food resources.

Grassle and Sanders⁹ think that in view of the known life history characteristics of deep-sea species, predation cannot be the principal mechanism for controlling population size. Recent investigations of numerous individuals belonging to single species of the tan-aid family Neotanaisidae, of the isopod family Desmosomatidae, and of protobranch bivalves showed small brood sizes and that each population is characterised by a much higher proportion of adults compared to young stages than encountered in comparable shallow-water species. Moreover, growth rate is slow and longevity high, as dramatically demonstrated by Turekian *et al.*¹⁰, who by using ²²⁸Ra chronology determined the age of a protobranch deep-sea bivalve, measuring up to 8.4 mm, to be about 100 yr. Small population size, low reproduction and mortality

Table 1 Composition of the macrofauna (% of the total number of individuals) at bathyal depths off Southern California and in the Arctic Ocean, at abyssal depths in the Atlantic and the Pacific, and at hadal depths in the Kurile-Kamchatka, Japan, Kermadec, and Java Trenches.

rates, and proportionately modest numbers in the smaller size groups would neither be expected nor have high survival value in predator-controlled communities or in any environment where transient diversity is important. These characteristics would, however, be expedient where long-term or evolutionary diversity is a product of past biological interactions in a physically stable environment such as that of the deep sea.

In order to arrive at a better understanding of the causes of deep-sea diversity, other methods must be applied, involving, for example, detailed analyses of microdistribution, nutrition, biochemical specialisation, and predator-prey relationships.

Construction of the box core sampler covering an area of 0.25 m² and partitioned into 25 subcores, each 100 cm², has made it possible not only to obtain quantitative data comparable with those obtained by bottom grabs (see below), but also to evaluate the microdistribution.

A comparison of core samples from the oligotrophic sea floor at 5,600 m in the central North Pacific Gyre showed a diversity of polychaetes and crustaceans exceeding that of sled samples from the oligotrophic north-western Atlantic¹¹. This high diversity in an extremely oligotrophic environment indicates that sparseness of food does not affect diversity.

Jumars¹² studied the polychaete fauna in partitioned box core samples from 1,230 m off Southern California and found that a uniform dispersal dominated within cores. Thus, the extremely high diversity observed cannot primarily be due to patchiness or spatial heterogeneity. But, species assumed to be sedentary (small-ambit species) were more diverse than species assumed to be mobile and thus having larger ambits. This indicates that microhabitat specialisation, acting on spatial scales smaller than 100 cm² (the area of the subcores), here has a major role in maintaining high polychaete species diversity. Similar results were obtained by comparing the entire fauna in box cores from two bathyal basins off Southern California¹³.

Composition and biomass of the deep-sea benthos

The grouping of benthic organisms into size classes reflects the sampling and processing techniques. Thus, it is generally accepted that the meiofauna comprises animals which are

retained on screens of about 60 µm and pass through screens coarser than 300-500 µm. The macrofauna is retained on the latter screens, while the megafauna consists of larger animals which cannot be collected adequately with a grab or core sampler for quantitative evaluation.

Fig. 2 One of many komoki from 6,100 m in the central North Pacific. It belongs to a new superfamily of agglutinating foraminiferans which have been found to be extremely abundant in the deep sea. Scale bar 1 mm. (After ref. 21.)

Most of these animals are large enough to appear in survey photographs.

The meiofauna: The number of living foraminiferans varies considerably regionally and with depth. Highest numbers (up to 1,400 per 10 cm² and 1 cm sediment depth) occur at bathyal depths off Southern California, while the mean numbers in the East Atlantic are an order of magnitude lower¹⁴. This is also the case in the Kurile-Kamchatka area, with highest numbers at bathyal and hadal depths and lowest numbers abyssally¹⁵. In contrast to other meiofaunal components (except to some extent the nematodes), a significant proportion of foraminiferans (up to 60%) lives in sediments deeper than the uppermost 1 cm (ref. 14). Calcareous foraminiferans dominate above about 2,000 m, while agglutinating forms are the sole components deeper than 3,500–4,500 m.

Comparisons of number of foraminiferans with the total meiofauna range from 2–27% foraminiferans off Mauritania at 250–4,500 m (ref. 14) to 2–90% (mean 61%) at 250–2,500 m (ref. 16) and 65% at 4,000 m (ref. 17) off North Carolina. In biomass, foraminiferans constitute 15–86% (mean 53%) in the Arctic Ocean¹⁸.

Except for local abundance of foraminiferans, the overall dominating group is the nematodes, in numbers as well as in biomass. Excluding foraminiferans, nematodes constitute 39–96% (mean 85%) of the meiofauna in the 165 compared samples and subsamples so far investigated from 11 areas at bathyal and abyssal depths. Dominance of nematodes does not seem to vary with increasing depth or distance from land.

Second in importance numerically are harpacticoid copepods, followed by polychaetes, ostracods, and crustacean nauplii. Rotifers, oligochaetes, bivalves and tardigrades may be present.

The density of organisms varies greatly, from 0.3 individuals per 10 cm² in the abyssal oligotrophic central North Pacific to 1,000–1,400 individuals per 10 cm² on the East and West Atlantic continental slope. The lowest biomass recorded is 0.1–0.05 g m⁻² surface and 4 cm sediment depth in the abyssal Mediterranean and the abyssal central North

Pacific, the highest is 3.5–6 g m⁻² at bathyal depths in the North Atlantic. At abyssal depths the biomass may be as high as 2.8 g m⁻² (the Norwegian Sea) and is usually 0.2–0.3 g m⁻².

Both numerically and in biomass there is a significant difference between the macro- and meiofauna with increasing depth. The marked macrofaunal decrease is not typical for the meiofauna. As mentioned above, meiofaunal biomass may be remarkably high at abyssal depths. Transect investigations in seven areas of the Atlantic¹⁴ show a maximum decrease of meiofauna biomass of 16–83% mean (50%) between upper slope and 3,000–5,000 m.

The macrofauna: A detailed analysis of 10 box core samples from two basins off Southern California (1,200 m) showed that polychaetes constitute more than 75% of the total number of individuals (Table 1). Next in importance are the peracarid crustaceans, with an almost equal share between amphipods, tanaids and isopods. Rather insignificant are bivalves and echinoderms (mainly consisting of brittle stars). In 75 quantitative samples from mainly bathyal depths in the Arctic Ocean half of all individuals (minus nematodes) were polychaetes (Table 1), followed by tetraxonid sponges (13%), crustaceans, and bivalves.

Also in abyssal communities, polychaetes, crustaceans, and bivalves generally are the main components of quantitative samples. In Table 1 the relative number of individuals in the marginal and oceanic north-western Atlantic and in the central North Pacific Gyre are compared. Polychaetes dominate, although in the oceanic environments they decrease somewhat in importance. The same applies to bivalves, while crustaceans, particularly tanaids, become proportionately more abundant. Combined, the three groups constitute 86–92% of the total fauna.

The above comparisons are based on box core and anchor dredge samples of the infauna. In epibenthic sled samples from the north-western Atlantic, which consist of both epifauna and infauna, a rather similar relative abundance prevails bathyally (Table 1), but at abyssal depths the composition is different. Polychaetes have an

Fig. 3 Quantitative distribution of zoobenthos (wet weight biomass) in the world oceans. (Slightly modified from ref. 23)

Fig. 4 About 3 m² of the sea floor at 1,800m depth SE of Massachusetts, USA. Alvin dive 685, 1976. Many brittle stars, *Ophiomusium lymani* (some in motion), white sea urchins, *Echinus affinis*, and one holothurian, Synallactidae. (Courtesy of Linda Morse, WHOI.)

inferior role. Brittle stars are very abundant in the more productive environments closer to the shore and are followed by cumaceans (another group of peracarid crustaceans). Bivalves dominate in the deep oligotrophic environment under the Sargasso Sea, followed by isopods. In Arctic Ocean sled samples from bathyal depths, sponges and polychaetes constitute nearly 25% each and crustaceans and ascidians 15% each¹⁸.

An evaluation of the composition of the hadal trench fauna cannot yet be based on quantitative data. Instead, Table 1 shows the average relative abundance of individuals collected in sled trawls in the four most thoroughly investigated trenches (which have an almost equal relative abundance). In these, and in all other trenches explored so far, the dominance of holothurians is as high as that of the polychaetes bathyally and in core/grab samples. Holothurians are followed in abundance by bivalves, polychaetes, and isopods. The preponderance of bivalves here and at 4,700 m in the north-western Atlantic (Table 1) may be due to winnowing during sampling at such great depths, resulting in loss of some of the lighter elements of the samples.

Two groups of protozoans of macrofaunal size, both agglutinating rhizopodes, are remarkably abundant, at least in some areas. The xenophyophores which are usually several centimetres in diameter may have pseudopodia extending 10–15 cm (ref. 20) and thereby be of great ecological importance. The other group is a hitherto overlooked, new superfamily, the Komokiacea (Fig. 2). These have a world-wide distribution, with a high relative abundance in hadal trenches and in the abyssal oligotrophic North Pacific. In the latter area their volume exceeds that of the metazoans and equals that of other foraminiferans²¹.

Extensive quantitative investigations in the Pacific²² show that polychaetes also constitute the dominant group at abyssal depths in biomass (up to 50%), although with the same decrease in importance in oligotrophic areas as was demonstrated when considering numerical abundance. Furthermore the biomass of crustaceans is relatively high in the oligotrophic areas (up to 25%) but almost obsolete in the productive areas. Similarly, echinoderms vary greatly in relative abundance and are nearly as dominant in weight in the south-western Pacific as the polychaetes. In the Arctic Ocean¹⁸, bivalves dominate in biomass (58%), and sponges (16%) are also more important than polychaetes.

The data of quantitative investigations demonstrate a pronounced decrease in total biomass with increasing depth

and distance from land, reflecting the reduced food input (Fig. 3.) Thus, 50 miles off California at about 200 m depth the total biomass is about 40 g m⁻², 50 miles further out, at 4,400 m, the biomass drops to 3.5 g m⁻²; a further decrease to 0.2–0.5 g m⁻² occurs 600 miles from the coast at about the same depth²².

In samples consisting of many small, equal-sized animals, numerical density is a better measure for biological biomass than the ordinary wet weight measurements which include inorganic shells of bivalves and skeletons of echinoderms and crustaceans. Comparable numerical densities are available from the north-western Atlantic and show the same marked decline, from 21,000 individuals per m² at the edge of the continental shelf and between 8,600 and 1,700 on the slope to only 30–150 individuals at 5,000 m under the Sargasso Sea and 200–700 on the slope of the oceanic Bermuda island group¹.

Exceptions to the general rule of macrofaunal decrease with depth and distance from land are the Arctic and Antarctic Oceans and deeper water off upwelling areas with a particularly high production in the euphotic zone. A relatively rich fauna also exists in most trenches close to continents and larger islands, probably because the trenches act as traps for organic material. Biomass as high as 40 g m⁻² has been reported from the Aleutian Trench²².

The megafauna: Photographic documentation, combined with trawling or collecting from submersibles, are recently introduced methods which supplement conventional trawling, thus allowing a more detailed and reliable evaluation of the composition and distribution of the epibenthic megafauna.

Series of bottom photographs from bathyal depths in the north-western Atlantic off the Carolinas²⁴ show dominance

Fig. 5 Grenadiers (macrourids) and possibly brotulids attacking bait on an extremely oligotrophic bottom, covered with manganese nodules, at a depth of 5,900 m in the central North Pacific. The width of the picture equals about 2 m. (Courtesy of John D. Isaacs, SIO.)

of the quill worm *Hyalinoecia* (up to 15 individuals per m² at 450 m) and the brittle star *Ophiomusium* (2–6 per m² at 1,700–2,200 m). Although nearly half of the identifiable species are echinoderms, only one other brittle star is abundant. Both brittle stars have a wide vertical distribution, while most other megafaunal species show the same narrow zonation as macrofauna species⁴.

Ophiomusium and *Hyalinoecia* also dominate at similar depths off New England²⁵ (Fig. 4). Except for a sea urchin, the other 28 identifiable species (17 of which are fish) are rare. At about 2,000 m the megafaunal numerical density is three orders of magnitude less than the macrofaunal density in anchor dredge samples.

Calculation of the biomass of the megafauna components in trawl samples from the same area²⁶ showed that macrofaunal and megafaunal biomass are, however, of the same order of magnitude. The most abundant taxa are fish and echinoderms. Generally fish dominate in number and particularly in weight at all depths (140–1,900 m), and their size increases with increasing depth.

In recent years an extraordinary abundance of large, mobile fish and other vigorous scavengers has unexpectedly been demonstrated in the deep sea by means of baited ballast and a camera suspended above the bait. Every 10 min a still photograph or motion pictures are taken, and after 24–48 hours the camera is automatically released and returned (using floats) to the surface.

This free-vehicle research has been conducted at almost all depths in all main oceans^{8,27}. At bathyal depths the usual sequence of events is first the appearance of large shrimps, brittle stars, and amphipods, followed about 30 min later by a variety of fish which often suddenly scatter because a very large sleeper shark (*Somniosus*) moves in. Crabs, sea urchins, snails, and so on are responsible for the final cleaning.

At abyssal depths fish and amphipods are the overall dominating scavengers. Large grenadier fish (*Coryphaenoides* and other macrourids) are very active (Fig. 5), while eelpout-like fish (Lycodidae) and brotulids remain almost motionless for a very long time or at most nibble gently at the bait. Lysianassid amphipods up to 28 cm long (twice as long as any amphipod previously known) were photographed at 5,300 m in the North Pacific²⁸ and at 7,000 m in the Peru–Chile Trench (Fig. 6). At 9,600 m in

Fig. 6 Multitude of amphipods and several shrimplike mysids gather around the bait at 7,000 m depth in the Peru–Chile Trench, stripping the bait in a few hours. (Courtesy of John D. Isaacs, SIO.)

Fig. 7 A thoroughly skeletonised bait fish and four of thousands of large, ravenous amphipods from traps set at 9,600 m depth in the Philippine Trench.

the Philippine Trench thousands of amphipods were attracted to fish bait, and subsequently more than 10 litres were caught in baited traps (my experience in 1975 on board R/V Washington of Scripps Institution of Oceanography). All belonged to one species of Lysianassidae (Fig. 7), of which only four specimens had previously been collected in the trench²⁹.

It is remarkable that scavenging fish and amphipods are particularly abundant in the central North Pacific Gyre, where the benthic standing crop is extremely low^{11,22,23}. The ubiquitous scavengers must therefore rely on large 'food parcels' descending from above, for example, dead bodies of fish and marine mammals and food fragments from surface-feeding fish. Once on the bottom, the food is quickly located and consumed by opportunistic scavenging fish and amphipods.

Amphipods caught in baited traps in the North Pacific³⁰ and in the Philippine Trench were all without broodpouch plates or eggs in spite of their large size. This fact suggests that onset of reproductive maturity may be conditioned by the intake of a large meal³⁰ and may be postponed until one such is available.

Nothing is known about the density of scavengers or the distance from which they are attracted to food. Obviously, in order to sustain this roaming fauna, larger amounts of 'food parcels' must reach the bottom than previously anticipated. In view of the abundance of scavengers, the faeces they disperse over the sea floor is probably an important source of energy for deposit feeders⁸, thus contributing to the maintenance of life in the deep sea.

Drugs from the sea—fact or fantasy?

P. T. Grant & A. M. Mackie

NERC, Institute of Marine Biochemistry, Aberdeen, UK

Drugs from the sea are as much a potential marine resource as cultivated fish, and mineral deposits. The study of the chemical structure and properties of unusual metabolic products of marine life is a subject where marine ecology and the experimental sciences of chemistry, biochemistry, pharmacology and medicine share a common and complementary interest. The development of ad hoc collaboration between specialists has advanced basic knowledge and resulted in a significant feedback to marine biology and ecology as well as in the development of some useful drugs.

OUR present armamentarium of drugs used to treat man and his domestic animals is mainly comprised of either natural products of unusual chemical structure and function derived from terrestrial microorganisms, plants and animals, or synthetic analogues of these products. Evolutionary adaptation has presumably resulted in metabolic diversity and cellular specialisation for their biosynthesis. In some cases it has been shown that these bioactive products of metabolism represent one mechanism of species survival in the highly competitive situations that can arise in natural ecosystems¹.

The clinical success of sulphonamides (Prontosil) and penicillin in the period 1938–45, led to a general acceptance of the idea that many human diseases would be amenable to treatment with selectively toxic chemicals. This led to the subsequent and successful search for new drugs. There is now some concern about the diminishing returns resulting from a continued emphasis on the screening of terrestrial life forms and a developing interest in the certainty that substances of therapeutic importance are to be found in the vast and diverse range of marine life—an estimated 500,000 species in 30 phyla. This certainty arises from the numerous reports of the pharmacological and toxicological effects elicited by extracts of marine organisms and from our knowledge of substances of ecological importance, such as the potent venoms and poisons concerned with offence and defence reactions. There is also a very extensive folklore and old records of a more or less anecdotal nature that are relevant to both human medicine and marine ecology^{2–4}. In this article, actual and potential therapeutic agents have been broadly classified as either 'antibiotics' that may be used to selectively control and destroy pathogens and parasites that cause disease, or systemic drugs that can modify or control body metabolism and function.

Antibiotics

Marine bacteria, fungi, phytoplanktonic and higher algae, as well as some invertebrates have been shown to contain antibacterial, antifungal and antiviral activities. The extensive literature on this subject has been reviewed^{2,3,5}. Some seasonal variation has been recorded. This would imply that the physical and chemical conditions of the microenvironment are critical for the expression of antibiotic activity by these organisms—a conclusion consistent with our extensive knowledge of the culture conditions necessary for the production of classical antibiotics such as penicillin.

In a study of the antibiotic activity of microorganisms isolated from various depths of the oceans (0–3,500 m), Krasil'nikova⁶ found that 124 of the 326 cultures collected were active against the test organisms *Staphylococcus aureus*, *Escherichia coli*, *Myobacterium luteum* and *Saccharomyces cerevisiae*. One actinomycete was also collected with a broad antibacterial spectrum. It is therefore not surprising that a variety of antibiotic activities have been observed in samples of filtered seawater³. At the same time relatively few studies have been taken to the point of isolation of the active principles involved. It is difficult to evaluate the relevance of most of these studies because the ratio of the minimum curative dose of the pure substance to the maximum tolerated dose for the infected animal is the first criterion used to determine the therapeutic potential of a substance with antibiotic activity. Moreover, in some cases, the active principle has turned out to be mainly of ecological significance, such as acrylic acid or brominated phenolic derivatives. One classical example of the potential of marine organisms has its origins in the observation that the culture fluid of a fungus, isolated from a sewage outfall into the sea, was toxic to a wide range of bacteria with an antibacterial spectrum similar to that of penicillin. Subsequently, Abraham, Newton and Florey showed that the fungus produced a number of antibiotics, notably a molecule containing a fused β -lactam-dehydrothiazine ring system (termed Cephalosporin C), as well as one with a fused β -lactam-thiazolidine ring system characteristic of the penicillin molecule⁷. Cephalosporin C and chemically-modified derivatives were toxic to a wide range of pathogenic bacteria, resistant to inactivation by the enzyme penicillin- β -lactamase and of low toxicity to man. Resistance to the inactivating enzyme was a very desirable property because a feature of therapy with penicillin was the development of strains of bacteria resistant to penicillin through selection of strains that produced the enzyme.

Other defined chemicals of marine origin with selectively toxic properties have been used in clinical medicine. Thelepin (a derivative of coumaran-2-spiro-cyclohexane, containing three bromine atoms per molecule) obtained from extracts of the polychete, *Thelepus setosus*, is an antifungal agent with a potency comparable to griseofulvin (a derivative of a coumaran-2-spiro-cyclohexane containing one chlorine atom per molecule), to which it bears a strong structural resemblance⁸. Kainic acid (2-carboxy,3-carboxymethyl,4-isopropenylpyrrolidine) is an efficient anthelmintic used in Japan to eliminate intestinal worms. Kainic acid is the active principle of the red algae, *Digenia simplex*⁹. Dried powders or syrups prepared from extracts of *Digenia* and other red algae have long been used as anthelmintics, with low toxicity to man, in Asia and in some countries bordering the Mediterranean⁹. The chemical nature and properties of antibiotics produced by marine organisms may well be the most rewarding area for definitive study in terms of human medicine. A programme of culture, screening, the selection of high-yielding strains and other development would require a considerable and broad-based effort, even if carried out in association with pharmaceutical companies who have experience with similar work involving terrestrial organisms. Apart from the speculative nature of such a venture, a purely mercenary aspect could limit support—as soon as the chemical structure of a drug is known an attempt can be made to make it available by

total chemical synthesis. While this can happen in some cases, most of our antibiotics such as the penicillins, streptomycin and tetracyclines are extremely complex structures and continue to be produced by the culture of high-yielding strains of microorganisms on a commercial scale.

Systemic drugs

There are about 2,000 venomous or poisonous species widely distributed among the marine fauna, with some concentration in tropical seas. The property of venom or poison biosynthesis is one mechanism that ensures species survival in densely populated ecosystems and represents a very successful form of chemical evolution and metabolic diversity from the common pattern. The general biology, chemistry and possible treatment of human illness caused by venom and by eating poison-laden fish, has been comprehensively reviewed by Halstead¹⁰. One of the most potent poisons known is tetrodotoxin (an amino perhydroquinazoline), a constituent of the liver and gonads of certain puffer fish (Tetraodon group)¹¹, porcupine fish (Diodontidae), ocean sunfish (Molidae), newts (Taricha) and some South American frogs. The flesh of the puffer fish is regarded as a great delicacy by Japanese gourmets, and a chef's reputation depends entirely on his ability to remove every trace of the toxic organs from the fish, and on the number of his guests who remain alive after eating his food. The dramatic and toxic effects of sampling sunfish roe is recorded by Captain Cook in his diary for 1774 (ref. 31). A lethal dose to man is about 10 µg per kg body weight and tetrodotoxin is about 160,000 times more potent in blocking axonal conduction than cocaine¹². It is extensively used as an inhibitor in neurophysiological research since it has a unique action on the gating of sodium channels or holes in excitable membranes. At low dosage levels, tetrodotoxin has been used clinically as a muscle relaxant and a pain killer in neurogenic leprosy and in terminal cancer³. It has also potential as a local anaesthetic¹³. The conclusion that tetrodotoxin is an endogenous fish poison¹¹ requires direct proof. Saxitoxin (a trialkyl tetrahydropurine derivative), is produced by strains of dinoflagellates of the genus *Gonyaulax* and has very similar but not identical pharmacological properties¹⁴. A massive overgrowth of these dinoflagellates and other phytoplankton can occur at certain times of the year in conditions that are not fully understood. This overgrowth develops to the point where the sea becomes discoloured and is termed a red-tide phenomenon. The bloom of phytoplankton can result in mass mortalities of fish due to toxins or to oxygen deprivation in the area of the bloom—but not of shellfish that consume the organisms and accumulate the toxin. This food-chain mechanism is presumably responsible for the periodic outbreaks of mussel poisoning or paralytic shellfish poisoning of man that have been recorded in recent years and in historical records¹⁴. It remains to be established whether saxitoxin is produced together with other toxins by the genus *Gymnodinium* which is also associated with red-tide phenomena. Apart from the venoms and poisons there are many reports that extracts of marine organisms have pharmacological effects on mammalian and other tissue preparations which can be described in such terms as anti-tumour, hallucogenic, neuroactive, cardioactive and cardiovascular^{2,3,5}. In some cases, the active principle has been identified. Interest in the ability of several genera of octopus to paralyse their prey by means of secretions from the posterior salivary glands led to the isolation of the peptide with the linear sequence, Pyroglu-Pro-Ser-Lys-Asp-Ala-Phe-Ile-Gly-Leu-Met-NH₂. This peptide from the salivary gland of *Eledone moschata* was termed eledoisin¹⁵, and proved to be a highly potent hypotensive agent in dogs—at least 50 times as active as histamine, acetylcholine and bradykinin on an equivalent

basis. Eledoisin and the related hexapeptide, Lys-Phe-Ile-Gly-Leu-Met-NH₂ (ref. 16), also stimulate extravascular smooth muscle and effect an atropine-resistant increase in salivary secretions. A cardioactive chemical, possibly an aromatic amine²² has been isolated in crystalline form from the branchial heart tissue of the primitive hagfish, *Eptatretus stoutii*¹⁷. The amine is a potent stimulator and pacemaker of the mammalian heart. This observation may be related to the fact that the heart of the hagfish consists of four pulsatile organs that operate independently—the systemic or branchial organ being aneural.

The possibility that some of the unusual metabolic products of marine organisms would have a selectively toxic action on tumour tissues in mammals remains an interesting possibility. Several have been identified, such as mercenene, a glycopeptide present in the common clam, *Mercenaria mercenaria*, during the summer months which is apparently non-toxic to mice at therapeutic levels¹⁸, and ill-defined substances present in the tentacles of two topical polychaetes¹⁹. The latter study would partly sustain the claims of folklore that cooked tentacles of *Lanice conchilega* had beneficial effects on certain forms of human cancer. One potent clinical anti-tumour agent has its origins in the discovery by Bergmann in 1968 that the West Indian sponge, *Tethya crypta*, contained large amounts of unusual arbinosyl-nucleosides. This led to the chemical synthesis and testing of a variety of nucleosides containing the unusual sugar moiety²⁰. 1-β-D-arabinofuranosyl cytosine (Ara-C) is a potent inhibitor of mammalian cell growth and is used extensively in chemotherapy in cancers such as leukaemias^{21,22}. Ara-C is known to be slowly phosphorylated to the 5'-triphosphate and has been shown to be incorporated into RNA and DNA and to inhibit DNA synthesis. Recently, a liponucleotide analogue, arabinofuranosylcytosine-5-diphosphate-1,2-dipalmitin has been synthesised and shown to be a potent inhibitor of leukemic cells (strain L 5178Y) in mice²³. It is claimed that cellular metabolism of the liponucleotide would generate Ara-CMP and hence the 5'-triphosphate at a faster rate than that resulting from direct phosphorylation of Ara-C by tissue kinases.

Attention has so far been concentrated on the nature and possible functions of the products of metabolic diversity and cellular specialisation in poikilothermic (cold blooded) marine organisms. Many patterns of metabolism are, however, common to all forms of life and certain hormones and other agents of metabolic control have a potential role in certain human disease states. In most cases these substances have been obtained from lower vertebrates sharing the same ultimate primitive ancestors as the mammals. One example was the extensive use of fish insulin, isolated mainly from the discrete islets of Langerhans of the tuna fish, to treat diabetics in Japan in the period 1939–45 (ref. 24). Other fish insulins, such as that of the cod *Gadus callarias*, have essentially the same specific hormonal activity in mammals as that of the homologous insulin. About 40% of the amino acid residues in cod insulin differ from those of bovine or porcine insulin but the invariant residues and features necessary for hormonal activity are conserved²⁵. In contrast, it was shown by Copp and others that the peptide hormone calcitonin, isolated from the ultimobranchial glands of the salmon (*Oncorhynchus*), was about 100–200-fold more active in man than the corresponding porcine hormone. This dramatic difference in activity has now been attributed to the greater resistance of the salmon hormone to degradation in the circulation of the mammal²⁶. A rather surprising development in recent years has been the discovery of relatively large amounts of prostaglandins in strains of the West Indian gorgonian, *Plexaura homomalla*²⁷, and in other marine organisms²⁸. The prostaglandins and thromboxanes constitute a family of related compounds that can be regarded as derivatives of the twenty-carbon atom monocyclic fatty acid, prostanoic acid.

These compounds were originally identified in mammalian tissue by Bergström in 1967 and have subsequently been implicated as the regulators of a very wide range of critical life processes in mammals, and in some disease states. Only trace amounts occur in the blood and tissues, both the prostaglandins and the thromboxanes, being formed by controlled biosynthesis from essential fatty acids through the intermediate prostaglandin endoperoxide. For this reason the gorgonians may well prove to be a useful starting material for chemical modification of prostaglandins to the mammalian types. This route may be a useful alternative to the successful but more complex process of total synthesis. An interesting feedback to marine biology is some evidence that the induction of prostaglandin synthesis (by hydrogen peroxide) is responsible for synchronous spawning in both male and female molluscs²⁹. It is thus tempting to speculate that the chemical signal effecting epidemic or synchronous spawning in the natural environment may be the concentration of oxidising free radicals generated by the light-induced photolysis of water.

Postscript

The only integrated proposals for the definitive study of a selection from the vast number of biologically active substances of marine origin have been oriented towards human medicine. A report to the Congress of the United States³⁰, contained a recommendation that a National Institute of Marine Medicine and Pharmacology should be established

as one of the National Institutes of Health. This recommendation has not so far been implemented, but a pharmaceutical company has recently opened a new laboratory in New South Wales, Australia—the Roche Research Institute of Marine Pharmacology.

Bioluminescence of marine organisms

Peter J. Herring

Institute of Oceanographic Sciences, Wormley, Godalming, Surrey, UK

Luminescence is a feature common to many marine organisms. Certain squid and fish utilise luminous bacteria as symbiotic sources of light, and the symbionts have physiological features which are of potential advantage in the association. The luciferins of some marine fishes, squids, crustaceans and coelenterates are of very similar chemical structure, though differing markedly from the luciferins of non-marine forms. Luminescence in many marine animals is probably used for ventral camouflage purposes.

THOSE whose lives have been closely associated with the sea and its resources have long been aware of both its general luminescence and that of many of its inhabitants. The first written record concerning luminescence of the sea has been attributed to Anaximenes (about 500 BC) and accounts of luminous marine animals have been available at least since the younger Pliny described the luminescence of *Pholas* and medusae¹. Bioluminescence has always been a source of wonder, often of awe, accentuated in earlier years by the conceptual difficulties of separating the phenomenon of light from that of heat. Indeed there is still occasional (unfounded) alarm that luminescent 'sparks' may trigger off explosions in oil tankers. By the mid-nineteenth century a variety of deep water marine animals had been taken which bore structures variously described as pores, slime glands or accessory eyes. It only became apparent that these

organs were for the production of light, rather than its perception, when the naturalists aboard HMS Challenger observed the emission of light from the ventral photophores of euphausiids and hatchetfishes². Only in this last century has the nature and occurrence of bioluminescence begun to be elucidated. Taxonomists have even occasionally enshrined the real (or sometimes imagined!) luminous abilities of many marine organisms in their names. Examples include *Photobacterium phosphoreum* (bacterium) *Pyrocystis* (dinoflagellate) *Pelagia noctiluca* (medusa) *Euphausia*, *Pyrocypis*, *Metridia lucens* (crustaceans) *Watasenia scintillans*, *Symplectoteuthis luminosa* (squids) *Pyrosoma* (tunicate) *Lampanyctus*, *Photoblepharon* and *Benthosema* (fishes). Even in common parlance lantern-fishes and fireworms provide marine counterparts to lighting bugs and fireflies.

This review deals briefly with three aspects of marine luminescence, namely the symbiotic luminous bacteria, the comparative chemistry of marine systems, and the use of luminescence as a camouflage.

Symbiotic luminous bacteria

All luminous bacteria require marine or other saline conditions, and they are present at all depths in the ocean, albeit in relatively small numbers. They can be grown in mass cultures in the laboratory and consequently more is known about the chemistry and molecular control of their luminescent system than that of almost any other organism^{3,4}. The luminescence of bacteria is normally continuous, with maximum intensity corresponding to a similar

Fig. 1 *Photoblepharon palpebratus*—the large light organ below the eye contains luminous bacteria.

maximum in luciferase synthesis. The initiation of luciferase synthesis is dependent on the accumulation of an auto-inducer in the culture medium; very dilute cultures do not luminesce⁴. Some cephalopods and many fishes have taken advantage of the availability of luminous marine bacteria and developed organs in which a population of these microorganisms is maintained, thereby providing the host with a symbiotic source of light. Two genera of luminous bacteria, *Photobacterium* and *Beneckea*, are currently recognised⁵. It seems that *Beneckea* includes only free-living strains, whereas all symbiotic strains should be included in *Photobacterium*⁵. It has recently been shown that the synthesis of the luminous system of some species of *Photobacterium* is enhanced at growth-limiting low oxygen concentrations⁶. This has obvious ecological significance in the symbiont's environment, as do other features of its physiology⁷, and is not the case in *Beneckea*⁸.

Some 60 yr ago enthusiasm for symbiotic bacteria as the source of animal light reached such a pitch that some investigators held it likely that all luminous organs contained symbionts. Symbiotic bacteria are now recognised as responsible for the luminescence of certain loliginid and sepiolid squids, and a considerable number of fishes. Most coastal luminous fishes utilise bacteria (Leiognathidae, Eretmophoridae, Acropomatidae, Steindachneriidae, Trachichthyidae, Monocentridae, Anomalopidae and some Apogonidae⁹). Bacterial systems are, however, also present in oceanic fishes at all depths, namely in the benthopelagic Macrouridae⁹, the mesopelagic Opisthoproctidae^{10,11} and the bathypelagic anglerfishes^{12,13}. In most fishes the luminous bacteria are associated with one or two gut diverticula. In the Anomalopidae and Monocentridae, however, each fish has a pair of bacterial organs, just beneath the eyes in the former (Fig. 1) and on the lower jaw in the latter. The other exceptions are the anglerfishes, in which bacteria are maintained in the esca, a luminous bulb placed at the tip of a modified dorsal fin ray. In the anglerfishes *Ceratias* and *Cryptopsaras* two or three more posterior fin rays are also modified into bacterial bulbs (the caruncles)¹³. All bacterial organs open to the exterior, either directly through a pore or through the gut lumen (Table 1). Although luminous bacteria from gut-associated organs are generally easy to culture on artificial media, self-luminous cultures have not yet been routinely obtained from either the Anomalopidae or the anglerfishes. Starvation of *Anomalops* leads to a gradual dimming and final extinction of its luminescence, correlated with a great reduction in the number of bacteria in the light organs¹⁴.

Animals utilising bacteria have particular problems with which to contend. The bacteria must be restricted to the particular organ, and not allowed to spread indiscriminately (luminous sand-hoppers suffering from a general uncontrolled infection of luminous bacteria are occasionally reported¹⁵). The culture must be maintained in good condition and without contamination by other bacteria. Some symbiotic strains produce antibiotic substances which may

inhibit contaminants¹⁶. Surplus or dead bacteria must also be removed. Most importantly the light organs of successive generations must be reinfected with the appropriate strain. While this presents little difficulty in gut-associated systems, the mechanisms used by other fishes, particularly the anglerfishes, are quite unknown. This may perhaps be a contributory reason for the very small number of light organs present in animals utilising bacteria. Bacteria luminesce continually, and some means of controlling the light emission from the organ is therefore necessary. This may be effected by obscuring it with chromatophores¹⁷, rotating the organ, occluding it with a shutter^{18,19} or by restricting its blood supply¹³.

In non-bacterial or intrinsic luminescent systems different organs tend to be used for different purposes. The very limited number of light organs present in animals using bacteria has resulted in a remarkable behavioural versatility in their use; the same organ may be used for prey illumination, escape from predators, and both schooling and sexual communication²⁰.

Comparative biochemistry of marine luminescence

The discovery in the seventeenth century of inorganic chemiluminescent systems, or 'phosphori', overlapped Boyle's classical investigations of the luminescence of rotting wood and meat, and for a long period subsequently all natural luminescence was generically ascribed to a 'phosphorus'. As late as the nineteenth century when Edward Forbes persuaded his friend George Wilson, the eminent chemist, to investigate the luminescence of the sea-pen *Pennatula*, Wilson concluded: "On the whole I believe it most probable that the animal secretes a spontaneously inflammable substance. It may be a compound of phosphorus, but it is not necessary to assume that it is"²¹. Organic chemiluminescent compounds were only discovered in the latter part of the nineteenth century, and were a necessary prelude to the understanding of the chemical nature of bioluminescence.

In 1887 Dubois demonstrated the luciferin-luciferase reaction on material from the mollusc *Pholas*²¹. It was subsequently found that this general reaction could be demonstrated in only a minority of species tested²². This led to the conclusion that a very large number of quite separate chemical systems had been evolved in different species. Even now the chemistry of very few luminous systems is understood in any detail^{23,24}. This to a considerable extent reflects the difficulties of obtaining adequate quantities of active material for investigation. For example, some 10,000 specimens of the medusa *Aequorea* were needed to produce 5 mg of the active protein²⁵, and 10,000 specimens of the squid *Watasenia* were also used in the initial isolation of its luciferin²⁶. Extracted chemical systems were, until very recently, apparently either of the luciferin-luciferase type or photoproteins. The latter are high molecular weight compounds which require no additional enzyme and emit light in the presence of oxygen and/or an

Table 1 Comparative features of bacterial and intrinsic light organs

Bacterial organs	Intrinsic organs
Restricted to a few squids and fishes	Widely distributed
Usually 1 or 2 organs (never > 4) per species	Often numerous (several thousand in some fishes)
Only one type in each species	May be several types in each species
Always open to the exterior	Often closed
Often associated with the gut	Not usually associated with the gut

appropriate trigger²⁴. In the case of aequorin, the most studied photoprotein²⁷, only calcium ions are necessary, and light emission will occur in the absence of oxygen. In other photoproteins, such as that from the polychaete *Chaetopterus*, molecular oxygen and other cofactors are necessary²⁸. The demonstration that either a luciferin-luciferase system or a calcium-triggered protein can be extracted from the sea pansy *Renilla*^{29,30}, depending on the methods used, and the fact that the 'chromophore' of aequorin³¹ is chemically very similar, if not identical, to *Renilla* luciferin³², has led to a reappraisal of the photoprotein concept³³. It now seems that photoproteins may be regarded as stable luciferin-luciferase complexes. If this complex remains stable when oxygenated then a 'pre-charged'³⁴ photoprotein such as aequorin is obtained³⁵. In general it is likely that the oxidation pathway proceeds through the formation of either a dioxetane^{3,33} or a linear peroxide³⁶.

The structure of the luciferin of the ostracod *Cypridina* was one of the first to be elucidated. It is an imidazopyrazine³⁷, and in recent years strikingly similar chemical structures have been found in a number of other marine luciferins. The luciferin of *Renilla* (and the chromophore of *Aequorea*) is a similar compound, as is that of the squid *Watasenia*³⁸, and the decapod shrimps *Oplophorus* and *Heterocarpus*^{39,40}. It is clear that these luciferins can be produced by the cyclisation of a simple tripeptide (composed of tryptophan, isoleucine and arginine in *Cypridina*), and a number of active model compounds have been synthesised using different combinations of amino acids⁴⁰.

A luciferin apparently identical to that of *Cypridina* has been found in a number of fishes including *Parapriacanthus*⁴¹, *Apogon*⁴², the midshipman *Porichthys*⁴³ and the lanternfish *Diaphus*⁴⁴. Ostracods were found in the gut of some *Parapriacanthus* specimens and as the fish stores its luciferin in gut diverticula it was suggested that the luciferin might be obtained from its crustacean food^{45,46}. Some support for this conjecture has come from recent work on *Porichthys notatus*. Californian populations of this fish are luminous, but Puget Sound populations are not—although they possess a full complement of photophores. They lack luciferin, but produce luciferase normally. When fed *Cypridina*, or injected with natural or synthetic *Cypridina* luciferin, they too luminesce normally⁴⁷⁻⁴⁹. This remarkable situation suggests the need for an exogenous source of luciferin for normal luminescence, or at least for its induction.

There is clearly a common link in the chemical nature of the luciferins of a number of taxonomically unrelated marine animals. Despite the fact that the luciferins of fireflies⁵⁰, the mollusc *Latia*⁵¹, the oligochaete *Diplocardia*⁵² and luminous bacteria have very different structures, it is nevertheless remarkable that luciferins with very similar structures have been obtained from four different marine phyla. It will be of great interest in the future to determine whether other marine species, many of whose systems have a superficial biochemistry rather different to that of *Cypridina* or *Renilla*, utilise luciferins of similar general structure.

The colour of the emitted light may be determined in a number of ways⁵³. Pioneer work on insects⁵⁴ and ostracods⁵⁵ showed that the colour of the light emitted during the oxidation of a luciferin is determined by the source of the luciferase. Changes in the molecular environment of the luciferin, whether brought about by attachment to the luciferase or by physical factors such as heat, cations or pH, can produce different emission wavelengths. Work with model luciferins of the *Renilla* type has shown that different degrees of ionisation, in turn partly dependent upon the particular tripeptide used, can give rise to very different emission maxima. It is therefore theoretically possible that different marine luciferins, derived from dif-

ferent tripeptides, could account for the observed variations in the colour of bioluminescence⁵³.

An intriguing feature of the luminous systems of some species is the presence of secondary emitters in the tissues. In these cases the energy of the luminescent reaction is transferred to a fluorescent material which then emits light at its own characteristic wavelength. Both *Renilla* and *Aequorea* contain a green fluorescent protein associated with the luminous tissue. *In vivo* light is green ($\lambda_{\max}$ 509 nm) but if the green fluorescent protein is removed a blue ($\lambda_{\max}$ 470–490 nm) *in vitro* emission is obtained. Addition of the green fluorescer to the *in vitro* system produces a green emission once more. Species lacking the green fluorescer (for example *Pelagia*, *Mnemiopsis*) emit only blue light both *in vivo* and *in vitro*⁵⁶⁻⁵⁸. Energy transfer has also been implicated in some fish⁵⁹ and squid⁶⁰ and may be responsible for bimodal emission spectra. It is tempting to consider that the red fluorescent proteins extracted from within the red-emitting photophores of the deep-sea fishes *Pachystomias Malacosteus* and *Aristostomias* may be involved in a similar process (P.J.H., unpublished).

Ventral camouflage

During the deep-sea expeditions of the late nineteenth and early twentieth centuries it became increasingly obvious that a great many deep sea animals bore light organs which were predominantly ventrally directed (Figs 2, 3 and 4). This is the case both in decapod crustaceans and in cephalopods, but is most prominently developed in fishes, both cartilaginous and bony. In 1916 Dahlgren, discussing cephalopods, noted "any animal situated below such a squid and looking upward at it from below would see a bluish light that would blend with the sunlight"⁶¹. Rauther applied the same hypothesis to fish⁶², but it was not until the idea of ventral camouflage was dealt with in detail by Fraser⁶³ and Clarke⁶⁴ that it achieved wide acceptance. In essence, animals living at depths still subject to background illumination from the surface are believed to illuminate their ventral surfaces so as to match the background, and eliminate the silhouette which would otherwise expose them to a predator from below. The use of this concept of ventral camouflage, or counter-illumination, was considered during World War 2 as a method of camouflaging planes during daylight sorties. Lights were to be fixed to their undersides to reduce or eliminate their silhouette, but the power requirement ruled out the idea at an early stage.

Recent work has been aimed at providing experimental support for this attractive hypothesis, but much of the

Fig. 2 The hatchetfish *Argyrops aculeatus*. The photophores are directed ventrally, with the exception of the preorbital organ (arrowed) which shines into the eye. This organ may act as a reference standard for comparison with ambient light.

Fig. 3 Ventral view of a luminescing *Argyropelecus olfersi*.

evidence is still circumstantial. Counter-illumination provides a rationale for the otherwise anomalous positions of numerous photophores. Many otherwise transparent squids have photophores beneath the eyes and ink sac, their only opaque organs. Many crustaceans also have photophores beneath the eyes. In decapods such as *Oplophorus* the photophores on the pereopods will contribute to the ventral illumination of the body when these limbs are folded in a swimming position. Ventral camouflage provides an explanation for the extraordinary anatomy of the mesopelagic fish *Opisthoproctus* (Figs 5, 6). The light from its single bacterial rectal organ is spread over the whole flattened sole of the fish by an elaborate light guide system^{10,11}. Similar anatomical diffusion of the light over the ventral surface is found in many other fishes utilising bacteria. The restricted number of light organs in such animals requires that elaborate accessory optical structures be present if a general ventral illumination is to be achieved^{17,64}.

Detailed anatomical and experimental studies of hatchetfish photophores have shown that their reflecting systems are so arranged that the angular distribution of the emitted light almost exactly matches that of the ambient downwelling daylight (Fig. 7)⁶⁵⁻⁶⁷. This arrangement ensures that the ventral camouflage is equally effective when observed from almost any angle. Hatchetfishes have a filter pigment, with a transmission maximum at about 480 nm, in the aperture of their photophores⁶⁸. Similar filter pigments are

Fig. 4 A lanternfish (*Myctophum* sp.) showing the ventral array of photophores (a) and its appearance when luminescing (b).

found in many other fishes, squids and crustaceans (Fig. 8). Measurements of the emission spectra of the photophores of certain fish before and after the removal of the filter pigments, have shown that the effect of the filter is to modify the emission spectrum so that it finally closely approximates that of the down-welling daylight (Denton, E.J., and Herring, P.J., unpublished). Some animals, at least, are therefore able to match both the angular and spectral distribution of ambient daylight. Such a system will obviously be most effective if the fish remains in a constant light intensity. It has indeed been demonstrated that some animals, in the form of scattering layers, remain very close to particular isolumens⁶⁹. Changes in ambient intensity also affect the depth distribution of many species, not only by day but also by night⁷⁰. If, on the other hand, an animal can alter the intensity of its own bioluminescence it achieves much greater behavioural flexibility, as its movements in the water column can then become independent

Fig. 5 Two specimens of the mesopelagic fish *Opisthoproctus grimaldii*. Luminous bacteria are maintained in a rectal diverticulum.

of diurnal changes in ambient light. Experimental evidence is now accumulating which indicates that in some animals at least the intensity of ventral bioluminescence can be varied. Free-swimming squid^{71,91}, ponyfish⁷² and luminescent fishes^{73,74} have been observed to alter their ventral luminescent output in response to changes in overhead light.

By what means does the animal ensure that its bioluminescent output matches the ambient light intensity? Many stomiatoid fishes have an orbital photophore that shines into the eye. It has been suggested that these organs allow the eye to 'light adapt' so that the fish is not blinded by its own emission⁷⁵. It seems more likely, however, that the function of this organ is to act as a reference standard for comparison with the light from above⁷⁶. Certainly, in hatchetfishes at least, the intensity of the orbital photophore waxes and wanes in concert with that of the ventral organs⁷⁷, a necessary feature of such a hypothesis. The supraorbital photophore in lanternfishes such as *Tarletonbeania* may also serve this purpose⁷⁸, while extra-ocular photoreceptors, the photic vesicles, may be similarly utilised in squids⁷⁸. Reference systems cannot however be identified in many fishes and other animals with ventral photophores. There seems no means, for example, whereby the upwardly directed eye of *Opisthoproctus* can detect the downwardly directed luminescence of its sole. It is possible that in such cases a fixed intensity emission may be modified by the responses of overlying chromatophores, and these in turn respond directly or indirectly to ambient light intensities. The colour and pattern responses of many shallow water fishes have an analogous feedback control requirement to the ventral bioluminescence of deep-sea species.

Fig. 6 The anatomy of the light organ of *Opisthoproctus soleatus* (from ref. 10). a, Lateral view showing the position of the light organ (l.o.) and light guide (l.g.). b, Detail of the light organ with its window (w) into the light guide, a hyaline tube surrounded by reflecting platelets (r) and diffusing the light over the whole area of the flattened sole (s).

Ventral counter-illumination can only be of camouflage value at depths in which downwelling light provides a significant background illumination, namely the epi- and mesopelagic zones²³. In the surface waters during the day the ambient intensity is too great to be countered by bioluminescence, and other aids to concealment, such as transparency, have to be used. Ventral illumination will be of greatest effect during the day in the mesopelagic zone, but at night will be equally effective much nearer the surface. The shallower living animals will need to emit more light than those in deeper and darker regions, and their respective ventral luminescent systems should give some indication of this. It was recognised very early that there is a correlation between the depth of a species and the development of its photophores²⁴. Murray and Hjort²⁵ noted that the fish *Cyclothone signata* had larger photophores than *C. microdon*, which was caught at greater depths. This is a

Fig. 7 A comparison between the angular distribution (in the transverse plane) of light from the hatchetfish *Argyrolepecus affinis* (●) and a computed curve for daylight in the sea (solid line) (from ref. 67).

general feature of many groups of animals, though it has only become clear with the advent of better techniques for the determination of the detailed vertical distribution of pelagic and planktonic organisms. Thus in *Cyclothone* the shallowest species *C. alba* and *C. braneri* have larger photophores than the deep *C. acclinidens* and *C. microdon*. The deepest species, *C. obscura*, has only rudimentary photophores. Similar series are found in species of *Gonostoma*, *Stomias*, the hatchetfishes, and the lanternfishes. In the latter group the photophores of the deeper genera (for example, *Lampadena*) are much smaller than those of shallower genera (for example, *Hygophum*, *Diaphus*). Similar traits occur in other groups. The deepest species of the euphausiid genus *Thysanopoda* have relatively much smaller photophores than shallower species, and in the

Fig. 8 Visible absorption spectra of pigments extracted from the photophore filters of four species of mesopelagic fishes. In each case the pigment is an effective blue filter, so that the final emission closely approximates the spectral distribution of ambient daylight in the sea. a, *Chauliodus sloani*; b, *Stomias boa*; c, *Valenciennellus tripunctulatus*; d, *Argyrolepecus aculeatus*.

shrimp genus *Systellaspis* the photophore size in different species also mirrors the depth distribution²¹. Some of the very deep living animals may use their photophores for camouflage only during their nocturnal migrations close to the surface.

Developmental information provides additional support. Many marine animals pass through a period as transparent larvae in the surface waters before sinking to greater depths as an adult. Those fish larvae that sink gradually during development tend also to develop their photophores gradually, with the result that they are appropriately equipped at all stages to mask their increasing opacity. Those that sink suddenly during a rapid metamorphosis tend to develop all their photophores at once, so that they, too, are equipped for their new light regime^{22,23}.

By no means all ventral photophores need be regarded as counter-illumination systems, and McAllister²⁴ has pointed out some of the problems inherent in any hypothesis of universal ventral camouflage. Many animals with ventral photophores are found close to the bottom during the day (for example ponyfishes). Counter-illumination would serve no purpose during the day—but might still be nearer the surface at night. Equally, if the orientation of of advantage in moonlit waters were the fish to migrate

a counter-illuminating animal changes in the water its camouflaging light could become a disastrous beacon. One of the stumbling blocks of a camouflage hypothesis is that submersible observations sometimes describe how many fishes seem almost randomly orientated in the water^{83,86}, though the animal may not necessarily be luminescing⁸⁷. Certain decapod and euphausiid shrimps can alter the orientation of their photophores^{88,89}, and this would be an effective means of compensating for changes in their orientation in the water. A further difficulty raised by bathysphere observations is the visibility of luminescing fishes. If their camouflage is effective they should not be visible. Yet Beebe⁹⁰ could "plainly see the lights of their (hatchetfishes) downwardly-directed photophores when the fish swam above me". These observations seem somewhat at variance with the camouflage concept of ventral luminescence. Nevertheless, there is now very considerable evidence, albeit still largely circumstantial, providing support for the hypothesis.

Observations of bioluminescence are always fascinating and often perplexing; their interpretations are even more so. Both observations and interpretations have a long history of suspicion, or outright disbelief. In the early eighteenth century a letter was received by the French Academy of Sciences from the people of Cadiz¹ "importing that . . . they had seen the whole sea shining with a clear light almost like a liquid phosphorus, . . . the seawater being carried away in bottles gave the same light in the dark; that some drops of it being let fall on the ground shone like sparks of fire, and that linnen dipt in this water became luminous." The Academy responded to this quite accurate description of dinoflagellate luminescence by retorting "The fact having been well examined, is found to be false, . . . The Academy think, they do as much service to the public, in disabusing them with regard to false wonders as in recounting to them the true." In which category would they have included the Puget Sound *Porichthys*, fishes with a complete battery of mainly ventral photophores—none of which work?

I thank Mr J. R. Badcock and Dr F. McCapra for commenting on the manuscript and Mrs C. Darter for preparing Figs 2 and 6.

A hundred years ago

RAINFALL OBSERVATIONS IN THE EAST OF FRANCE FROM 1763 TO 1870.—In the *Bulletin Hebdomadaire* of the Scientific Association of France, of the 10th instant, Prof. Raulin gives an interesting historical account of all the rainfall observations made during these 108 years anywhere in that section of France which is marked off by lines joining Givet on the Meuse, Lauterbourg on the Rhine, Belley near the Rhon, and Decize on the Loire, and which thus comprehends seven well-marked regions, viz., the plain of Alsace, the chain of the Vosges, the plateaux of Lorraine and Bourgogne, the plains of Champagne and Bresse, and finally the chain of the Jura mountains. During the past three years Prof. Raulin has been engaged collecting all available materials for a monograph on the rainfall of this part of Europe, which, judging from his great monographs of the rainfall of other sections of France and of the rainfall of Algeria, will doubtless take its place as a permanent contribution of very high value to meteorological science.

Marine research in China

Bertil Öström

National Board of Fisheries, Hydrographic Department, Fack, 40310 Göteborg, Sweden

This paper is a personal travel report from a visit to the People's Republic of China in September and October 1976. Oceanographic research, as seen from visits to institutes, participation in fieldwork and personal contacts, is discussed, with some emphasis on the physical and chemical aspects. There is a tangible striving for utility in research policy. Research activities are also to a large extent integrated with other functions of society. Marine research is of increasing importance in China today; there is a growing cognisance of the hazards involved in pollution of the marine environment. The technical standard varies; some institutes are equipped with older apparatus based on manual methods, whereas others had access to modern analytical instruments. Information about the important centres for oceanographic research, at Tsingtao on the Yellow Sea coast and at Kwangchow for the south China Sea is presented.

THE sea is of great historical importance in Chinese society. It has been a temptation as an escape out of a land locked by mountains to the west. It has also carried enemies in warships to the long China coast.

The Chinese have long been eminent seafarers. The most renowned of them was Cheng Ho, alias San Pao (he is best known under the latter name in Asia and on the Southern islands). From the mouth of Yangtze Kiang he started enormous trade expeditions with 500-foot ships and more than 20,000 men in the beginning of the fifteenth century, that is before Diaz, Vasco da Gama, Columbus and Magellan. Cheng reached India, Persia and Ethiopia. On later voyages he visited Zanzibar to the East of Africa and Timor near Australia.

Later there was a decline in Chinese seafaring. Internal antagonism during the Ming dynasty led to a prohibition of long voyages and all ships with more than two masts were broken up. The Chinese command of the sea was thereby irretrievably lost. The Portuguese and the Dutch soon became the new commanders of the seas. Later there followed a period of lively sea traffic to China (but without Chinese participation), and during the following centuries parts of the Chinese coast were colonised. Not until this century with the liquidation of most of the colonies (some of them, for example Hong Kong, are still left) has a new Chinese merchant navy grown up. Today this merchant navy is of a considerable size, often sailing under the flag of convenience of Somalia or Panama. Local river navigation has always been important and the transport of goods by junks has been the core of the Chinese transportation network.

The sea has long been a source of nutriment for the Chinese. The profession of the fisherman is mentioned in the oldest documents. Even more characteristic of the old Chinese knowledge of the sea is the use of marine algae for food. Algae are collected at sea and included in the fare where they are either eaten directly or cooked. Some

are preserved or dried and stored for later use. More than a hundred species are used for food.

Supply of resources from the sea

Interest in the sea is today focused on natural resources. The question, what can the sea give up in the way of food, minerals and energy? is being raised all over the world. When it comes to extraction of food from the sea we are today departing from the hunting stage where we catch whatever we can, to the farming stage where we plan and breed aiming at maximal yield but with protective measures taken to support the regrowth. In this field China has a great advantage in the knowledge that is accumulated from freshwater farming. For many thousands of years the Chinese people have collected information about fish breeding in ponds, of how to master the diseases of fish and of how to best feed and catch. Some of this knowledge can be transferred to conditions in the sea. Regarding

Fig. 1 Sketch map of China. The coastline is approximately 10,000 km long. Tsingtao on the Shangtung peninsula is a centre for marine research. Large mussel farms are kept in the shallow water of the Yellow Sea outside the town and marine algae are cultivated on beds in the tidal zone close to the shore. The Pohai Sea and Yellow Sea are steadily silting up (Shangtung was formerly an island and Peking was situated at the sea) due to mud deposits from the northern rivers. Kwangchow has several marine institutes and is now a centre for present research activities in the South China Sea.

minerals and energy, China, like many other countries, is now aware of the potential richness of the sea. Sea areas which were previously fairly uninteresting become suddenly valuable and territorial demands are raised and fishing rights are claimed.

Marine research

In these circumstances it is natural that marine research in China is expanding. Research institutes are growing, new vessels are built, field stations are established and new problem areas are investigated. My journey to China with visits to various marine institutes was arranged to study marine research and to get a view of its status today. It was a research exchange between China and Sweden and a group of Chinese scientists had the opportunity to study the corresponding Swedish conditions.

A comparison of research policies shows difference of principles between China and the 'Western countries'. In the West we have an extensive basic research and a parallel applied research which sometimes, when needed, uses results from the basic research. This basic research is sometimes termed free research and the applied research is called

Fig. 2 The research vessel, The Red Star, anchored on the Pearl River near Kwangchow (Canton): 66 m length, 11 m width, 3.7 m depth, 1500 tons dead weight, 12 knots. It takes 100 tons of freshwater and 120 tons of fuel allowing expeditions of up to 3 weeks at sea with a crew of 35 (sailors and scientists). Many of the cruises are directed to the South China Sea. Home harbour is Kwangchow.

technical research. Free research is based on personal interests of individual scientists who find a certain problem area interesting. These scientists apply for finance from the scientific boards directing the research, are supplied with grants and make an investigation resulting in a report. In this way knowledge of previously unknown conditions is documented to form a field of knowledge where the gaps, one after the other, are filled in. The individual scientist at the time of the investigation may not necessarily see of what direct use the knowledge he accumulates can be. It is known empirically that basic research is profitable by creating a base for technical development, and the scientist can assume that the knowledge might come to use some time in the future.

This so called free research is not emphasised in China. Instead, research is strongly directed at problems. The investigation is expected to give a practical result as soon as possible and is therefore more like our technical research. The reason for this probably lies in Chinese modern history,

where the overall dominating aim was to free the population of over 800 million from starvation (a task carried out within one human generation). In this situation all marine research was aimed at an increase in the yield of nutriment from the sea, and it is possible that increased basic research will return with increased economic margins. It is probable that a weak basic research in the long run will check the applied research. On the other hand, the question can be raised as to whether we in the Western countries sometimes solve hypothetical problems that consume resources but are of no practical importance. Probably we have a lot to learn from each other. If we learn and take advantage of the pronounced utility in the Chinese research and the broad base for technology provided by the Western research, we should find a good formula for truly effective research.

A distinct impression from the collaboration with the Chinese scientists is that they are well aware of the events and progress of science in the West, but that they carefully sort out and make use of only the results that in some way are fit and good for China. Many of the senior scientists have, after the liberation, returned from institutions in USA and Europe. They master foreign languages, have a good overview of the research situation in the Western countries and today they often have leading positions in their institutes. The flow of information from Western literature is sufficient and the institution libraries often have the later important works in the field of marine research. Yet there are no signs of Americanisation or strong European influence in research policy and methods. As a visitor one gets, after a while, a strange feeling of being 'looked through'; one realises that the Chinese colleagues fairly well know one's situation without being interested in taking it over.

Fig. 3 Shanghai harbour. To the right the fore-end of a modern trawler. The signs mean Shanghai Fishing Company and are followed by a number. In the background modern trade ships and in front of them traditional wooden sailing junks carrying goods up the Yangtze Kiang river.

There is also an interesting difference regarding research means and methods. We can, in our countries, hardly purge ourselves from new ideas and methods which are pushing on, regardless of if we really should prefer them or not, whereas the Chinese society has found ways completely to control and direct outside influence.

There is a great interest in China throughout the world. Academia Sinica who mediate the scientific visits receive many applications from groups wanting to visit China, and they strain off a considerable part. But there is today a great Chinese interest in Western methods, knowledge and experience in the areas of pollution studies and environmental protection.

Much of the equipment at the research institutes consists of simple, sometimes almost primitive aids, much apparatus is worn out and also the basic resources like buildings and fixtures are often old and worn. On the whole, the technical standard is quite low. This depends partly on an actual low standard, but partly also on the thinking based on optimisation and utility that is found everywhere in China; human and material resources should be used in a judicious way, overdone technology has no mission; all activities should aim at an improvement of the vital conditions for the people.

Fig. 4 Buoy systems carrying nets on which blue mussels grow in the mussel farms south of Tsingtao in the Yellow Sea. (Photograph by Hans Ackefors).

On the other hand there is no lack of resources 'when they are needed', that is, when a problem is considered urgent. If, say, an unknown disease were to threaten the huge marine cultivation farms on the coast, large resources of personnel, research vessels and modern instruments would be available to attack the problem. Laboratory instruments were sometimes amazingly modern in design and function. As an example there were Chinese manufactured scanning recording spectrophotometers and gas chromatographs with linear temperature programming and all types of interchangeable detectors including electron capture. The instruments had also advanced industrial design in their performance, which is an indication of a high technical level. These instruments were manufactured in Shanghai.

Chinese marine research has access to a number of research vessels making regular cruises at sea. The Yellow Sea, being a productive shallow water area on the shelf has traditionally seen the main part of the research activities with a centre in Tsingtao on the Shangtung peninsula. The East China Sea coast has some importance for fishing and cultivation of algae. Today, however, the interest is largely concentrated on the South China Sea. This is caused by the increased awareness of the fish resources in the area and the recent discovery of potential oil and mineral resources. Field stations have been established on previously unoccupied groups of islands and an intensive investigation programme concerned with the marine geology, hydrography and fishery biology of the area has started. Unfortunately, it was not possible to visit the most interesting research vessel, the Red Star, as the ship was on a cruise to the South China Sea. The photograph, Fig. 2, was taken by another Swedish visitor (Olof Tandberg); it shows the Red Star which is approximately 2,000 tons dead weight.

Information was also obtained on two newly built ocean-going research vessels of approximately 10,000 tons dead weight, which were at that time on expeditions in the Pacific. These ships are controlled directly by the central government in Peking. Information on these ships has also been given in the information journal *Peking Review*, published in English in several countries. The ships have equipment for marine geological investigations and laboratories for chemical analyses. There are also many smaller research vessels, many of which operate in connection with field stations on the coast. In addition, research work and practical work are to a large extent integrated in China, so that, for example, fishing boats take samples for later analysis at the research laboratories.

Visits to marine research institutes

Practical oceanographic research work was studied during visits to a number of research institutes along the coast. A certain formalism and conformity characterised all such visits. The visit is introduced with a quiet chat where everybody is drinking tea, sitting in a rectangular formation along three of the four walls of the room. The talk is, however, mainly directed by the group leader of the visitors and the head of the reception committee, and does not have the form of a general discussion.

During continued tea drinking the political objectives of the institute are then thoroughly described by the political representative of the reception committee. It is obvious that chairman Mao's thinking has had and still has an immense influence on all activities in China. All institutes visited lean back on his statements as directives for their work. Some political concepts often recur. One such concept is the 'trinity' which can refer to peasants, workers and soldiers, for example, in discussions of recruiting students to the universities, or it can sometimes denote other constellations such as workers, technicians and supervisors in discussions of a technical problem. The fact that an instrument is constructed by an engineer, the assembly is planned by a supervisor and performed by a worker is in our language convention understood; we know it, but we do not say it. In China, it is felt important to underline such facts, to mark a new approach, a difference from the past, and when displaying an instrument these three anonymous but equal originators are mentioned.

Another concept is 'open-door research' which underlines the cooperation between research and production. The scientist should not retire into splendid isolation when solving his problems but carry out his research in the industries cooperating with the workers and considering their practical viewpoints of the problem.

After the information on the political objectives follows an account of the scientific research program, given by a scientist of the institute. Thereafter follows a guided visit to the different laboratories to see the activities and equipment. There is an open atmosphere during these visits, questions are answered, everything is shown on request, improvisations and suggested changes of the program are acceded to as far as is reasonable. (This was also the case for the free time during the programme. There were no restrictions on the movements and activities of the visitors.)

Apparatus and technical equipment

Chinese research laboratories have different, not so strict, partitioning into disciplines compared with that which we are used to. Problems which we would have split up into, say, a biochemical and a marine geological part, may in China be solved at the same place. The partitioning of fields of activities and translations of laboratory names made in the following are therefore often approximate and difficult to bring close to reality.

The research vessel the Red Star (Fig. 2) has a common water sampling equipment, with deep-going winches and water samplers, instruments for observation and measurements of physical properties, tube and gram samplers for sediments and laboratory on board for chemical analysis. Part of the equipment is carried on board for every expedition, for example, the photometer. There is also a laboratory for treatment and conservation of biological samples.

The institutes visited all had laboratories for analysis of water samples which were brought back from sea. Shantung Institute for Oceanography had a modern salinometer, based on electric conductivity of the sea water, of high sensitivity ($S = \pm 0.001\%$). This institute manufactured for calibration purposes, standard sea water which was sealed into glass ampoules.

As mentioned above, some institutes were equipped with modern gas chromatographs and spectrophotometers. Access to mass spectrographic analysis was also provided, although we did not see an installation during the visits. At Shantung Institute for Aquatic Products a cold atomic absorption instrument for a.o. mercury determinations was demonstrated.

The sampling equipment shown at some institutes was of conventional types. Russian designed grab samplers for sediment were shown in Kwangchow, and common types of plankton nets were also to be seen.

The basic equipment of the laboratories such as centrifuges, drying ovens, microscopes, water thermostat baths and oscilloscopes was in the main similar to what we are used to in our laboratories for routine oceanographic analyses.

The carbon-14 technique for measurement of the primary phytoplankton production was known and was studied at Hupeh Hydrobiological Institute at Yangtze Kiang. It was not yet in use at sea, however, and the primary production was determined according to the oxygen method using light and dark bottles.

Remote sensing as a tool in marine research is as yet very little used in China. The scientific element of the country's own satellite program is (according to verbal communication) merely used for studying meteorological problems. It has been said that China is probably taking information from the LANDSAT-satellites, but comments on that were not received.

Pollution problems are receiving an increasing interest as a result of the increased pollution by industrialisation. The scientists are aware of the problems and anxious to learn from other countries and share their experiences of solutions to the problems. It is unlikely that they will allow a mercury and cadmium catastrophe like that in Japan.

It is admitted, however, that DDT is a serious problem and that even deaths have occurred. Intensive research in the area of biological control is going on in order to replace the chemical biocides with biological control methods. Instrumentation for routine analysis of heavy metals and for DDT was seen at many laboratories.

The Institutes

The Institutes carrying out oceanographic research were the following.

South China Sea Institute of Oceanography in Kwangchow (Canton), is administered by Academia Sinica. It specialises in the South China Sea and has laboratories specialising in hydrography and meteorology, marine geology, marine biology and hydrophysics.

The institute was founded at Chanchiang on the south coast but was moved to Kwangchow in 1973. This institute

is administering the research vessel, the Red Star. It has also been engaged in pollution studies. There are 340 employees, including those in field stations. A new building for the institute comprising six floors of a total of 9,000 m² for research and administration is under construction. Another research vessel of about 1,000 tons is being built this year.

Kwantung Institute for Aquatic Products in Kwangchow. The institute specialises on the South China Sea. The main task is to develop and utilise the resources of the South China Sea. It has about 500 employees, most of them stationed on field stations belonging to the institute. A new building is under construction for the mother institute in Kwangchow, which will contain a political office, an administrative office and six laboratories. The institute has several smaller research vessels. One branch of their activities is also to spread scientific information among the people.

Shanghai Institute for Aquatic Products in Shanghai. The Institute had, after the cultural revolution 1968, no research vessels of its own, but its scientists are working from fishing boats in cooperation with the fishermen and the fishing company (open-door research). About 200 are employed. The Institute has a laboratory for marine resources.

Tsingtao Institute of Oceanology in Tsingtao. The institute belongs to Academia Sinica. Their working area is the entire coast from Pohai to the South China Sea. About 500 persons are employed. They have three research vessels of 1,000, 400 and 300 tons dw respectively and laboratories for marine physics, marine geology, marine chemistry and oceanographic research instruments. The institute is also engaged in pollution studies. Research is to some extent concentrated on the Yellow Sea shelf area. Sediment movements are also studied.

Shantung Institute of Oceanography in Tsingtao. The institute is mainly an educational institution. There are departments of marine hydrology and meteorology, marine physics, marine chemistry, marine geology and marine biology. There are about 500 employees and the number of students varies during the year. There are 840 places for a 3-yr education for marine scientists. There are also about 1,000 students on short term courses. Education is also given by correspondence. The institute has stressed work on pollution and environmental problems. For field work and excursions there are a number of small motor-boats.

Shantung Provincial Institute for Marine Products in Tsingtao, with about 220 employees. Working area is the Pohai Sea and Yellow Sea. Emphasis is on the living resources. Research is on effects of industrial sewage water on the marine environment.

Direct reference to Chinese scientists, and further details of marine research in China may be obtained from the author on request.

I thank The Royal Swedish Academy of Sciences and the Swedish Academy of Engineering Sciences for a fellowship, and Academia Sinica in Peking, for a well planned programme. Thanks are also due to the tour conductor, Mr Lu Ching-ling, and the interpreter, Mr Chu Chian-ning, and to Drs Bern Dybern, Hans Ackefors and Anders Jarmen and to Ann-Louise Martin for many fruitful discussions. Dr Olof Tandberg kindly submitted photographic and scientific material, and Mr Bertil Kuhlemann provided much useful information.

Possible relation between optical and very long baseline interferometer radio observations of the QSO 3C 345

T. D. Kinman

Kitt Peak National Observatory, Tucson, Arizona 85726

Existing radio and optical data on the variability of the QSO 3C 345 are summarised. Interesting correlations between the polarisation in radio and optical bands are evident; moreover successive outbursts have similar polarisation. This suggests that all outbursts are triggered by activity in the same central object rather than being a consequence of unrelated explosions of supernovae or similar objects.

SEVERAL QSOs show an apparent superrelativistic expansion in the radio which often continues for several years along the same position angle. On one interpretation, the expansion must be guided by a relatively permanent structure, and I have, therefore, looked for other signs of this structure. During outbursts, the annual mean plane of polarisation of the optical radiation from 3C 345 aligns with the direction of the superrelativistic expansion: the magnetic field associated with the optical radiation is therefore perpendicular to the expansion. There is weaker evidence that in the radio the average intrinsic plane of polarisation is perpendicular to the expansion vector. These regularities give more support to the idea that a QSO has an ordered and relatively stable structure than that it is made up of an array of unrelated sources.

Superrelativistic expansion

3C 345 (redshift 0.595) is one of the three QSOs in which radio variability was first discovered by Dent¹. Its optical variability² was discovered soon afterwards, and also its associated property of a variable optical polarisation³. It has therefore been one of the most closely monitored sources at both optical and radio wavelengths. Recently, very long baseline interferometer (VLBI) radio observations at 2.8 cm by Cohen *et al.*⁴ and by Wittels *et al.*^{5,6} at 3.8 cm have shown that apparent superrelativistic expansion occurs in this source. Between 1974.15 and 1976.13, Cohen *et al.* found a separation increase of from 1.23 to 1.70 milliarc s on a two-component model. Wittels *et al.* found a separation increase of from 1.0 to 1.3 milliarc s from late 1971 to 1974 at the longer wavelength. In both cases, the position angle of the expansion was well defined with a position angle $105^\circ \pm 5^\circ$. Explanations of such expansion have been suggested in terms of (1) relativistic motion along the line of sight⁷, (2) a static array of sources whose flux variations simulate the expansion⁸, or (3) a model in which it is the phase motion of an actual expansion that

is observed^{9,10}. The second explanation requires that contractions should be observed as frequently as expansions, and this is not the case as far as is known. Sanders¹¹ has described a model of the third type in which the superrelativistic effect is produced by synchrotron emission from electrons travelling in a dipole magnetic field as seen from its equatorial plane. Each expansion originates from a relatively impulsive injection of relativistic electrons from a source near the centre of the dipole. The energy of these electrons is less than the energy of the magnetic field, and so the field survives, and the same expansion orientation may be expected for successive outbursts.

It seems likely that the impulsive injection of the electrons should be associated with an increase in the optical flux. A simple linear extrapolation back to zero component separation suggests that the present expansion originated between 1958 and 1963 (3.8-cm observations) or at about 1967 (2.8-cm observations). The time of origin is therefore quite ill-determined. Furthermore, if the beaming angle of the optical flux is very small (1–10 mrad) as suggested by Cocke and Pacholczyk¹², the actual optical emission associated with a specific radio expansion might

Fig. 1 Optical flux and linear polarisation properties of 3C 345: *a*, monthly means of the optical flux in mJy; *b*, annual means of the position angle θ of the polarised flux; and *c*, annual mean of the percentage polarisation.

Fig. 2 The residuals of the normalised Stokes parameters for the optical flux from 3C 345 after removal of their annual mean values.

be missed if it did not occur in the direction of the Earth. But even in this case, if the model has a permanent magnetic structure, each optical event should carry in its linear polarisation the signature of the magnetic field geometry and this should be related to the geometry of the expansion.

Optical linear polarisation

Some 114 observations of the optical linear polarisation of 3C 345 have been made between 1967 and 1974, inclusive, by Elvius¹³, Visvanathan¹⁴, Babadzhanyan *et al.*¹⁵, Kinman *et al.*¹⁶, and unpublished observations by the author. This polarisation is characterised by quite large changes which can occur on time scale as short as a few days. To smooth out such changes in a search for systematic effects, annual means of the normalised Stokes parameters (Q_m/I , U_m/I) were formed and used to compute the annual mean polarisation P and the annual mean position angle θ of the optical E-vector. These are shown in Fig. 1; the error bars are the r.m.s. deviations of these means. The distribution of the residuals ($\Delta[Q/I]$, $\Delta[U/I]$) from these means is shown in Fig. 2. Systematic trends (for example, skewness in the distribution of these residuals) may be present, but seem small enough for the means (Q_m/I , U_m/I) to have enough significance for our present purpose. These annual means and their residuals corre-

spond roughly to the slowly varying component B and the rapidly varying component C in the more elaborate analysis by Kinman *et al.*¹⁶. In the top panel of Fig. 1, the monthly means of the optical flux S are given in mJy; they were derived from B -magnitudes given by Kinman *et al.*¹⁶, Barbieri and Abati-Erculiani¹⁷, Lü¹⁸, Babadzhanyan *et al.*¹⁵, Tritton and Selmes¹⁹, and unpublished observations by the author using the relation

$$\log_{10} S = 6.67 - 0.4 B$$

Two substantial outbursts are seen. One began in October 1966 (Kinman *et al.*¹⁶) and ended in 1968, and the second has its maximum in the second half of 1971. The sparse data available from old plates (Angione²⁰) do not contradict the idea that outbursts of this kind are occurring at a rate of about one every five years. It has been suggested by C. Barbieri, G. Romano, S. di Serego and M. Zambon (personal communication) that an actual period of 4.38 yr is present. It does not seem unlikely that these outbursts are associated with the large injections of electrons that give rise to the expansion phenomenon on Sander's¹¹ model. An injection event rate much higher than this would presumably result in the superposition of several expanding radio sources at one time. If the rate was much lower, the expansion phenomenon would be rarer than we observe.

The optical position angle shows some regularity in its behaviour—lying between 80° and 110° when these major outbursts occur. The emission in a highly polarised source of synchrotron radiation must come from an optically thin plasma and will have the E-vector perpendicular to the magnetic field. The field associated with the optical radiation is therefore perpendicular to the expansion direction and (on Sander's model) to the axis of a dipole field. If we speculate that the central source is a massive body with its rotation axis parallel to the axis of the dipole field, the optical radiation could come from an equatorial field on the massive object. In order to account for periodic effects in the optical flux of 3C 345, Kinman *et al.*¹⁶ speculated that the slowly varying component B (which is large when the optical flux is high) arises in the equatorial zone of a rotating body.

Radio polarisation

Radio polarisation data from 1971 to 1975 are shown in Fig. 3. A rotation measure of 18.3 rad m^{-2} (Haves²¹) was applied to the 3.7- and 11.1-cm data of Altschuler and Wardle²², and the 6-cm data of Seielstad and Berge²³. On Sander's model, we would expect the relevant magnetic field to lie predominantly parallel to the expansion direction, and so would expect a position angle for the radio linear polarisation of 15° if the plasma is optically thin, or 105° in the optically thick case. If the field is a permanent structure, the position angle should not show a large secular trend, and this is observed. While the optically thin case does agree better with the observations, it does not seem possible to apply the usual criteria of an expanding cloud model (particularly if beaming effects are present) to decide whether the source is, in fact, optically thin or not. We only note that if it is optically thin for most of this time, then the excursion of the position angle for the 3.7- and 6.0-cm data during 1973 and 1974 (and the simultaneous drop in the percentage polarisation) can be understood in terms of the transient appearance of an optically thick component at these wavelengths.

The present optical and radio data are therefore compatible with models of 3C 345 which involve a relatively permanent structure, and in which sustained relations between the polarisation planes of the radiation and the expansion direction may be expected. Clearly, in any one object, the agreement could be entirely fortuitous, and the

Fig. 3 Radio linear polarisation properties of 3C 345: *a* the percentage polarisation [at 3.7 cm, and *b*, the position angle (corrected for Faraday rotation) at 11.1 cm (○), 6 cm (×), and 3.7 cm (●).

crucial test will be to see if similar relationships can be found in other QSOs. It can also be said that the presence of long term systematic polarisation effects does not give support to QSO models that involve an array of unrelated sources.

I am grateful to Barbieri *et al.* and Cocke and Pacholczyk for sending me preprints before publication.

The Kitt Peak National Observatory is operated by the Association of Universities for Research in Astronomy, Inc., under contract with the NSF.

A gating signal for the potassium channel?

R. H. Adrian & A. R. Peres

Physiological Laboratory, University of Cambridge

It is suggested that some part of the intramembrane charge movement in striated muscle is associated with the opening and closing of the potassium channel.

THE control of several membrane processes has been associated with small asymmetric displacement currents which may signal intramembrane charge displacement or dipole movement. Schneider and Chandler¹ reported a charge movement in striated muscle which they suggested could be associated with activation of contraction or possibly with activation of potassium conductance². Armstrong and Bezanilla³ and Keynes and Rojas⁴ have investigated the 'gating' currents associated with the activation of sodium conductance in the giant axon of the squid. We report here experiments on the charge movement in striated muscle (sartorius muscle, *Rana temporaria*) which show that it may be separated into two components; one has approximately first order kinetics, and the other has kinetics which seem to associate it with the potassium channel.

Measurement of charge movement

Sartorius muscles were examined in a solution designed to minimise all ionic currents and to prevent contraction. The solution was made hypertonic with sucrose and contained tetraethylammonium ion (TEA) and tetrodotoxin to eliminate sodium current and potassium current⁵. The composition of the solutions was Rb₂SO₄, 5 mM; TEA Cl, 15 mM; (TEA)₂SO₄, 80 mM; CaSO₄, 8 mM; sucrose, 350 mM; TTX, 10⁻⁷ M (ref. 6). Three electrodes inserted close to the pelvic end of a fibre were used to apply exponentially blunted steps of potential ($\tau = 1$ ms, duration 128 ms) to the membrane at the end of the fibre¹. Records of the total current (I) injected into the fibre, the membrane current (i_m) as the potential difference (ΔV) between the two potential measuring electrodes ($i_m = 2\Delta V / 3l^2r_i$, where l is the electrode separation), and the membrane potential (V) at a distance l from the end of the fibre were taken by digitalising the signals and filing them on the disk of a PDP 11 computer. Using this information appropriate programmes calculated the linear membrane constants and displayed nonlinear membrane currents on the computer oscilloscope. Photographic records were also taken of the analogue signals from the fibre to display the complete sequence of prepulses and measuring pulse. Membrane resistance and internal longitudinal resistance (r_i) were calculated from the steady-state values of I , V , and ΔV from a 10-mV control step. The membrane capacity was calculated from the internal

resistance (r_i) and the integral of the transient membrane current (ref. 6)

$$C_{\text{eff}} = \frac{2}{3l^2r_iV} \int_0^\infty \left[\Delta V_i(t) - \frac{\Delta V(\infty)}{V(\infty)} V(t) \right] dt \quad (1)$$

All experiments were done at 2–4 °C.

The detection of charge movement is best done by subtracting the membrane currents required for two identically shaped steps of potential. One of these steps, the test step, is in a range of membrane potential where charges or dipoles are moved by a change of potential: the other, the control step, is ideally in a range where the charges are not moved. For instance one can apply two pulses of different magnitude both starting from the same potential, a potential at which the charge movement is saturated. Alternatively one can apply two pulses of the same size but starting from different potentials. If the steps are not the same size the currents require appropriate scaling before subtraction. The subtraction removes currents in linear membrane elements; linear ionic currents and linear polarisation current in the membrane dielectric due to induced dipoles. Movement of charged molecules or dipole reorientation will in general be nonlinear if a sufficient potential range can be explored. Nevertheless, the subtraction method can only give the difference between the charge moved in test and control pulses, so that if charge moves in the control pulse because the pulses are at insufficiently separated potentials or because there are several species of charges moving the interpretation of nonlinear current may be difficult.

The central sets of records in Figs 1 and 2 are proportional to the non-linear membrane current ($i_m'(t)$) which is defined by

$$i_m'(t) = \frac{2}{3l^2r_i} \left[\Delta V_i(t) - \frac{V_i(\infty)}{V_c(\infty)} \Delta V_c(t) \right] \quad (2)$$

where the subscripts t and c refer to test and control potential steps. In Fig. 1 both control and test steps start at -90 mV: the control step is +10 mV and the positive going test step is variable. This procedure with four control steps and one test step is the same as that used by Adrian and Almers⁸ to study the charge movement they called Charge 1. In Fig. 2 the control pulse is +10 mV from -90 mV: the test pulse is +10 mV from a membrane potential displaced in a positive direction by

Fig. 1 *a*, Records of I , ΔV and V show a representative sequence of test and control pulses. *b* and *c* were generated by a PDP 11 computer and photographed from an oscilloscope. *b* Shows asymmetrical displacement currents

$$i'_m(t) \times \frac{3l^2 r_i}{2} = \left[(\Delta V_i(t) - \Delta V_c(t)) \frac{V_i(\infty)}{V_c(\infty)} \right]$$

produced by test pulses to an internal potential of -70 , -60 , -55 mV and so on. *c* Shows $d(n^4)/dt$ calculated for steps from -90 mV to -70 , -60 , -55 mV and so on (see text). Calibration lines for the computed traces are 50 ms for both traces; 10 mV for experimental traces and 0.033 ms^{-1} for $d(n^4)/dt$. Fibre 1501: l , 500 μm ; r_i , $21 \pm 0.7 \text{ M}\Omega \text{ cm}^{-1}$; R_m , $11.4 \pm 0.4 \text{ k}\Omega \text{ cm}^{-2}$; C_m , $6.0 \pm 0.1 \text{ }\mu\text{F cm}^{-2}$; diameter, $48 \pm 0.8 \text{ }\mu\text{m}$; temperature, 3.7°C . Fibre constants are means ($\pm$ s.e.m.) of five control steps of 10 mV at beginning of experiment.

a prepulse. In both Figs 1 and 2, the central column of records (*b*) shows the non-linear currents which result during and after the pulse when the potential range from -90 mV to 0 mV is explored. As has been reported previously^{2,8}, integration of the transient non-linear current for the 'on' and the 'off' of the step gives approximately equal charge movements, suggesting a capacitative origin for the current.

Fig. 2 As in Fig. 1, but the asymmetric displacement currents are generated by subtracting the ΔV records for two 10 mV steps starting from different potentials. Calibration lines are 50 ms; 3.3 mV for experimental records and 0.01 ms^{-1} for $d(n^4)/dt$. Fibre 1302: l , 500 μm ; r_i , $13.5 \pm 0.6 \text{ M}\Omega \text{ cm}^{-1}$; R_m , $8.7 \pm 0.3 \text{ k}\Omega \text{ cm}^{-2}$; C_m , $5.6 \pm 0.2 \text{ }\mu\text{F cm}^{-2}$; diameter, $61 \pm 1.5 \text{ }\mu\text{m}$; temperature, 2.5°C .

In both Figs 1 and 2 the nonlinear current is most easily described in terms of two components. For increasing depolarisation during the test step (Fig. 1) or for increasing depolarisation preceding the test step (Fig. 2) one sees first a transient current which is maximal immediately following the 'on' of the step and decays more or less exponentially with a time constant of a few milliseconds. The reverse movement at the 'off' of the step is similarly exponential. At about -50 mV one begins to see a hump of current which occurs first in the middle of the step (that is maximum at about 60 ms from the beginning of the step). At the same potential there is a marked increase in the size of the exponentially decaying current at the 'off'. The hump of current is also clearly visible in the analogue record of ΔV (left hand column of Fig. 2). Over the next 10 mV of depolarisation the hump of current occurs earlier and becomes shorter and higher until eventually both 'on' and 'off' current transients decay more or less exponentially. Figure 1 shows the measured charge movements which take place between -90 mV and a series of more depolarised potentials: Fig. 2 shows the measured charge movements which take place in successive 10 mV intervals of the potential range -80 mV to -10 mV.

In both Figs 1 and 2 at membrane potentials between about -45 mV and -35 mV, the charge movement during the pulse can be described in terms of an exponentially decaying component together with a slower component which rises slowly and then falls. There is, however, no way to separate the components unambiguously and in particular no way of knowing whether, if there are two components, the initial value of the slowly developing movement is finite or zero. Nevertheless, it is evident that the slower charge movement during the voltage step is not well described by a first order process, though the movement after the voltage step might be.

The potassium conductance (g_K) is known to turn on with high order kinetics and off with first order kinetics^{7,9}. It seemed worthwhile, therefore, to see how far the charge movements in Figs 1 and 2 could be predicted by Hodgkin-Huxley kinetics¹⁰. In their description of the potassium conductance changes in the squid axon

$$g_K = \bar{g}_K n^4 \quad (3)$$

$$dn/dt = (1-n)\alpha_n - n\beta_n \quad (4)$$

$\bar{g}_K$ is a limiting conductance and α_n and β_n are rate constants depending only on the membrane potential (V). n^4 can be thought of as the probability that a potassium channel is in the open configuration. Adrian, Chandler and Hodgkin⁷ described the potassium conductance measured in sartorius muscle fibres at $1-3^\circ\text{C}$ with equations (3) and (4) and the rate constants at 3°C

$$\alpha_n = \frac{0.0044 (V+40)}{1 - \exp[-(V+40)/7]} \text{ ms}^{-1} \quad (5)$$

$$\beta_n = 0.0185 \exp[-(V+40)/40] \text{ ms}^{-1} \quad (6)$$

Figure 3 (which is reproduced from ref. 7) shows α_n , β_n , n_∞ (or n_0) and τ_n^{-1} where n_0 and n_∞ are given by

$$n_0 = \frac{\alpha_{n0}}{\alpha_{n0} + \beta_{n0}} \quad (7)$$

$$n_\infty = \frac{\alpha_{n\infty}}{\alpha_{n\infty} + \beta_{n\infty}} \quad (8)$$

and

$$\tau_n = \frac{1}{\alpha_{n\infty} + \beta_{n\infty}} \quad (9)$$

Fig. 3 *a*, Relation between n_{∞} (from steady-state potassium conductance) and membrane potential. Open circles represent experimental points: the line is calculated from

$$n_{\infty} = \frac{\alpha_n}{\alpha_n + \beta_n}$$

b, Relation between rate constants (τ_n^{-1}) obtained from records of potassium currents produced by depolarisation (○) and repolarisations (●) to different potentials: the line is calculated from

$$\tau_n^{-1} = \alpha_n + \beta_n$$

The dotted lines are calculated by equations (5) and (6). (Figure reproduced from ref. 7.)

For a step change of potential from V_0 to V_{∞} the solution to equation (4) is

$$n = n_{\infty} - (n_{\infty} - n_0) \exp(-t/\tau_n) \quad (10)$$

Hodgkin and Huxley¹⁰ suggested that movement of four independent particles onto a potassium channel precedes its opening. The movement of each n particle was described by equation (4). On this basis one would expect to detect an exponentially decaying charge movement (i_n) whenever the potential was changed abruptly which would be given by

$$i_n \propto (dn/dt) = \tau_n^{-1} (n_{\infty} - n_0) \exp(-t/\tau_n) \quad (11)$$

If the actual opening of a potassium channel involved the redistribution of other charges in the membrane field, or the entry of additional charges into the membrane, then in addition to the charge movement reflecting the preliminary and rate-limiting process there would be a charge movement associated with the opening process. This would resemble

$$\begin{aligned} \frac{d}{dt}(n^4) = & \frac{4(n_{\infty} - n_0)}{\tau_n} \left[n_{\infty}^3 \exp\left(\frac{-t}{\tau_n}\right) \right. \\ & - 3n_{\infty}^2 (n_{\infty} - n_0) \exp\left(\frac{-2t}{\tau_n}\right) + \\ & + 3n_{\infty} (n_{\infty} - n_0)^2 \exp\left(\frac{-3t}{\tau_n}\right) \\ & \left. - (n_{\infty} - n_0)^3 \exp\left(\frac{-4t}{\tau_n}\right) \right] \quad (12) \end{aligned}$$

Different kinetic models could be made to generate different combinations of exponential terms. Equation (12) by itself could not describe the total charge movement since it implies that the n process does not involve charge movement and therefore could not be potential dependent.

Figure 4 plots $i_m'(t)$ from Fig. 1 at a test potential of -43 mV and compares with it dn/dt and $d(n^4)/dt$ calculated by equations (5) to (12) for a potential step from -90 mV to -43 mV at a temperature of 4°C (Q_{10} for rate constants was assumed to be 2.5). The two calculated curves have been arbitrarily scaled. It is clear that the charge during the test step could be described by an arbitrary combination of dn/dt and $d(n^4)/dt$. But it is equally clear that this would not be a unique description. It would, however, be difficult to describe the charge movement in terms of either function alone.

Fig. 4 The points are values of $[3I^2 r_1 i_m'(t)]/2$ derived from a control step of $+10$ mV and a test step of $+47$ mV both from -90 mV. The dash-dot line is dn/dt , the dotted line $d(n^4)/dt$ both calculated from equations (5) to (12) at 4°C . They are arbitrarily scaled so that the curves coincide in the latter part of their time course during the voltage step. Note that although the voltage step was blunted with a time constant of 1 ms, the calculated curves assume a sudden step. The points which are taken from the experiment in Fig. 1 are at 1-ms intervals on the horizontal axis: the vertical scale is in mV.

The right-hand columns of Figs 1 and 2 give $d(n^4)/dt$ calculated for the voltage steps of the experimental records. They show the extent to which later parts of the charge movements resemble the differential of n raised to a power greater than the first. In Fig. 1, $d(n^4)/dt = 0$ at the beginning of the step since n_0 at -90 mV is effectively zero. In Fig. 2 at the beginning of the 10 mV test step n_0 is not equal to zero and for $t = 0$

$$\frac{d}{dt}(n^4) = \frac{4n^3_0(n_\infty - n_0)}{\tau_n}$$

Figure 5 extends the similarity between part of the detected charge movement and $d(n^4)/dt$. In Fig. 5a and b charge is moved between the same potentials but in opposite directions: both charge movement and $d(n^4)/dt$ are approximately exponential when the potential change is negative, $d(n^4)/dt$ and part of the charge movement are humped when the potential change is positive. Figure 5c shows the charge movement when the potential changes from -32 to -42 mV: Fig. 5a shows the charge movement at the same potential but when the potential changes from -52 to -42 mV. Though the charge movement takes place at the same potential its time course depends on the direction of movement. The same kind of difference is seen in $d(n^4)/dt$.

Separation of charge movement into components

The question arises whether all or only part of the initial and approximately exponential charge movement seen in the experimental records should be associated with the more complex later charge movement. It would be difficult from the records to separate the charge movement into components. But in striated muscle it is known that the potassium conductance inactivates with time. This inactivation resembles, but is much slower than, the inactivation of the sodium conductance. Adrian, Chandler and Hodgkin¹⁷ have shown that the potassium conductance is about 70% inactivated when the membrane potential is held at -40 mV. If the membrane potential is held at -40 mV, but stepped to -90 mV for a 'control' +10 mV pulse and to other membrane potentials for 'test' 10 mV pulses, then the detected charge movement seems to consist of an early exponential component only. The voltage distribution of this moved charge (Q against V curve) does not resemble n_∞ being less steeply voltage dependent and with a transition potential at about -15 to -20 mV. The shape of this curve

Fig. 5 As in Fig. 2, but showing that configuration of displacement current depends on its direction. Calibration lines are 50 ms; 3.3 mV for experimental computer traces and 0.01 ms⁻¹ for $d(n^4)/dt$. Fibre 1303; l , 500 μ m; r_i , 11.8 ± 1.3 M Ω cm⁻¹; R_m , 14.3 ± 0.6 K Ω cm⁻²; C_m , 11.9 ± 0.2 μ F cm⁻²; diameter, 66 ± 3.2 μ m; temperature 2.6 °C.

resembles that postulated by Adrian, Chandler and Rakowski¹¹ to account for repriming of contraction after long depolarisation.

If the membrane potential is held at -20 mV both contraction and potassium conductance are inactivated and if charge movement is examined over the same potential range (-90 mV to 0 mV), both early exponential and late slow charge movements are absent. This effect of holding potential charge movement was first reported by Chandler, Rakowski and Schneider¹². It seems possible therefore that part, at least, of the early and exponential charge movement may be related to contraction and that the later slow charge movement as well as an undetermined part of the early more or less exponential charge movement may be related to the potassium channel.

In what follows we shall refer to this latter current as the opening signal or current, making the plausible but unproved assumption that it is a signal from the potassium channel. The implication is that external TEA blocks the potassium channel by combining with an external site on the channel^{5,13} but leaves unaltered the opening and closing of an internally located gate. The opening of this gate is associated with a movement of charge in or perhaps into the membrane: its closing with an equal and opposite movement of charge.

How many charges move when one channel opens? To estimate this quantity we need to know the conductance of a single potassium channel. We shall assume a value between 10^{-12} and 10^{-11} S (ref. 14). If the total opening charge is 10 nC μ F⁻¹ and the membrane capacity is 5 μ F cm⁻² the charge is 50 nC cm⁻² of fibre surface. When this amount of charge has moved, in the absence of TEA the potassium conductance would be 20 mS cm⁻² (ref. 7). If the channel conductance is 4 pS (ref. 15) each opening event is associated with the movement of 60 charges. This figure is no more reliable than the rather uncertain quantities on which it is based, but it seems to exclude the possibility that the opening current is due to the entry of an internal TEA ion or other internal ion into the blocked channel when the gate opens¹⁶. Equally, though it might be consistent with models which involve the association of several multiply charged molecules in the opening process, the magnitude of the opening signal is unexpectedly large¹⁷.

In previous studies the charge movement in normally polarised muscle has been called charge 1 (refs 2, 8, 17). Chandler, Rakowski and Schneider^{2,12} gave careful consideration to an association between charge 1 and potassium activation but felt that there was insufficient evidence for a firm conclusion. Nonetheless, though comment has been made on the complexity of its kinetics¹⁸, charge 1 has been tentatively considered to be one species of charge and more likely to be associated with contraction activation than potassium channel activation¹⁷. Our results suggest that charge 1 may be two distinct charge species. Movement of one of these charges is an approximately first order process and this charge remains a candidate for being a regulator of contraction activation. The second charge could be associated with the potassium channel. The kinetics of this second charge movement favour an association with the opening of the potassium channel. But the size and complex time course argue against any simple link of the kind suggested by Hodgkin and Huxley¹⁰. Moreover, it is still possible that the detected charge movement is related to some high order process other than potassium gating.

We thank EMBO for the award of a Fellowship to enable A.P. to visit Cambridge, and the *Journal of Physiology* for permission to reproduce Fig. 3.

DNA complementary to parathyroid mRNA directs synthesis of pre-proparathyroid hormone in a linked transcription–translation system

Henry M. Kronenberg, Bryan E. Roberts*, Joel F. Habener, John T. Potts, Jr & Alexander Rich

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139 and Endocrine Unit, Massachusetts General Hospital, Boston, Massachusetts 02114

DNA complementary in sequence to the messenger RNA for pre-proparathyroid hormone was synthesised using reverse transcriptase. In a linked transcription–translation system using RNA polymerase and cell-free extract from wheat germ, the DNA directed the synthesis of a protein identified as pre-proparathyroid hormone by N-terminal sequencing and by electrophoretic and immunologic criteria.

PARATHYROID hormone (PTH) is a small polypeptide of 84 amino acids that is of critical importance in the regulation of calcium levels in the extracellular fluid of higher vertebrates (see ref. 1 for review). In the parathyroid gland, PTH is first synthesised as a precursor of 115 amino acids, pre-proparathyroid hormone (Pre-ProPTH) (ref. 2). During or shortly after synthesis *in vivo*, Pre-ProPTH undergoes two consecutive proteolytic cleavages, resulting in the formation of PTH through an intermediate precursor, parathyroid hormone, a polypeptide of 90 amino acids³. Both proteolytic cleavages occur at the amino-terminal end of the precursors. The primary structures of PTH and the two biosynthetic precursors have been determined^{4–6}.

Previously we have prepared and characterised the messenger RNA for Pre-ProPTH (refs 4, 5, 7). Using reverse transcriptase, we have now synthesised DNA complementary in sequence (cDNA) to this message. Recently, several investigators^{8–10} have developed conditions for using reverse transcriptase to synthesise cDNA molecules as large as their mRNA templates. We have used similar conditions and report here that the cDNA is large enough to direct the synthesis of Pre-ProPTH in a linked transcription–translation cell-free system. The cDNA was transcribed using wheat germ RNA polymerase, and the newly synthesised RNA was then used to direct protein synthesis in a cell-free extract. Control experiments showed that this synthesis was not due to contamination of the cDNA by the initial mRNA. The Pre-ProPTH synthesised was characterised by molecular sizing on polyacrylamide gels, specific reactivity with antiserum to PTH, and amino-acid sequencing at the N terminus.

DNA-directed Pre-ProPTH synthesis

Complementary DNA was synthesised from partially purified Pre-ProPTH mRNA using conditions similar to

those described by Efstratiadis *et al.*⁸ (see legend to Fig. 1). Electrophoresis in a 5% polyacrylamide–98% formamide gel showed that the cDNA is heterogeneous in size, with a major species containing almost 800 nucleotides. Its characterisation will be described more fully elsewhere. The Pre-ProPTH mRNA was not characterised in detail here, but earlier studies indicated that it is approximately the same size as the cDNA (refs 4, 6).

We tested the ability of the cDNA prepared from Pre-ProPTH mRNA to direct the synthesis of Pre-ProPTH in the linked transcription–translation system. After treatment with alkali to hydrolyse the RNA, the cDNA stimulated the synthesis of a protein that co-migrated with Pre-ProPTH on a SDS–urea, 15–20% polyacrylamide gradient gel (Fig. 1c, d). The synthesis of this protein was dependent on the addition of wheat germ RNA polymerase (Fig. 1b). Moreover, all of the proteins synthesised in the absence of RNA polymerase co-migrated with those that were synthesised by the wheat germ extract in the absence of any added nucleic acid (Fig. 1a, b).

The incorporation of ³H-UTP into trichloroacetic-acid-precipitable material was dependent upon the addition of RNA polymerase to the cDNA (Table 1). It was reasonable to conclude that this newly-synthesised RNA was translated into Pre-ProPTH, but other possible alternatives had to be examined. For example, the polymerase might have stimulated the synthesis of non-functional RNA that protected from degradation some of the original mRNA present as a contaminant in the cDNA preparation. Therefore, experiment 2 in Fig. 1 was performed in the presence of carrier transfer RNA (1 mg ml⁻¹ during the transcription), and the results make this explanation unlikely. The synthesis of Pre-ProPTH required the presence of RNA polymerase (Fig. 1e, g), even though carrier tRNA was included in each incubation. Alternatively, the polymerase might have removed contaminating mRNA from a cDNA–mRNA hybrid, allowing the mRNA to bind ribosomes and undergo translation. These possibilities and most other explanations that postulate contamination of the cDNA preparation with mRNA were eliminated by treating the cDNA preparation with DNase. Complementary DNA treated with pancreatic DNase during the transcription did not stimulate protein synthesis in the linked transcription–translation system (Fig. 1e, f). The possibility that the effect of DNase was not due to digestion of cDNA, but rather due to the action of contaminating RNase was excluded. In the conditions of the incubations, mRNA added separately to the reaction with DNase retained 84% of its original activity (Table 1).

*Present address: Department of Biology, Brandeis University, Waltham, Massachusetts.

contained 2 A_{260} units ml^{-1} Pre-ProPTH mRNA, four deoxyribonucleotide triphosphates, 1 mM each, and ^3H -dCPT adjusted to 0.4 Ci mmol^{-1} . Avian myeloblastosis virus reverse transcriptase was kindly supplied by J. W. Beard. After 3 h at 43 °C, the reaction mixture was adjusted to 0.1 N in NaOH and incubated for another 16 h at 37 °C. After neutralisation of the NaOH with an equal amount of HCl and adjustment to 0.1 M in Tris-HCl (pH 9.0), the nucleic acid was extracted once with an equal volume of phenol-chloroform-isoamyl alcohol and passed over a 5 ml Sephadex G1-50 column in H_2O . Fractions eluting in the void volume of the column were pooled, adjusted to 0.1 M NaCl and precipitated with 2 volumes of ethanol. In experiment 2, but not in experiment 1, a mixture of purified wheat germ tRNA provided by T. Fraser, was added at 50 $\mu\text{g ml}^{-1}$ as a carrier before the ethanol precipitation. The conditions used for the linked transcription-translation reactions were similar to those described previously^{11, 12} except that the transcription reaction was carried out for 1 h instead of 15 min. Each reaction mixture contained approximately 0.1 μg DNA, estimated from the specific activity of ^3H -CTP. In experiment 2 (channels (e)-(h)), assuming 100% recovery, the tRNA added as carrier was present at a concentration of 1 mg ml^{-1} during transcription and 0.2 mg ml^{-1} during translation. Addition of larger amounts of wheat germ tRNA to the reaction mixture inhibited translation. Different preparations of cDNA were used in each of the two experiments. ^{35}S -methionine was used as the radioactive amino acid. After the translation reaction was completed, the proteins in 5 μl of each 50 μl extract were analysed by electrophoresis on 15–20% polyacrylamide, SDS-urea gels²⁴ followed by fluorography²⁵. Gels were exposed to Kodak SB-5 film for 3 d at -70 °C. Experiment 1: channel a, no DNA; b, no wheat germ RNA polymerase added; c, cDNA and RNA polymerase added; d, 0.04 μg mRNA added directly to 50 μl of the translation reaction mixture. Experiment 2: channel e, cDNA, RNA polymerase and tRNA added; f, same as (e) plus pancreatic DNase 0.1 mg ml^{-1} added during transcription; g, same as (e) without RNA polymerase added; h, same as (e) without cDNA or tRNA. O, origin; P, PreProPTH; BPB, bromophenol blue dye front.

Fig. 1 Polyacrylamide gel analysis of two experiments demonstrating Pre-ProPTH synthesis in a linked transcription-translation system. Calf parathyroid glands were frozen in liquid nitrogen within 30 min of killing. Subsequently, they were ground to a powder in a mortar chilled with dry ice. While still frozen, 10 volumes of 0.05 M Na acetate (pH 5.0), 0.01 M EDTA, 0.5% SDS, and heparin (100 $\mu\text{g ml}^{-1}$) were added along with an equal volume of phenol:chloroform:isoamyl alcohol (1:1:0.4) and the mixture was allowed to thaw to room temperature. All extractions were carried out at room temperature. Three extractions with the phenol:chloroform:isoamyl alcohol mixture were performed, followed by three extractions with chloroform:isoamyl alcohol (24:1), and finally by precipitation with two volumes of ethanol overnight at -20 °C after adjustment to 0.2 M with NaCl. The nucleic acid was dissolved in 0.5 M NaCl, 0.01 M Tris-HCl (pH 7.5), 0.5% SDS, then passed over a column containing 1.0 ml of oligo-dT-cellulose (T-3, Collaborative Research) for every 50 A_{260} units of nucleic acid. (1 A_{260} defined as the amount of nucleic acid that has an absorbance of 1 at 260 nm, when dissolved in 1 ml of water and measured through a 1-cm light path.) The column was eluted with 0.01 M Tris-HCl (pH 7.5), 0.5% SDS. The eluant was adjusted to 0.5 M NaCl, bound to and eluted from the column of oligo-dT a second time, precipitated in ethanol, and then centrifuged through a linear gradient of 5–20% sucrose in buffered 50% formamide as described²³. Fractions collected from the gradient were assayed for mRNA coding for Pre-ProPTH using the wheat germ cell free system⁸, and fractions containing maximum activity were pooled. The predominant, but not exclusive protein made from this preparation of mRNA was Pre-ProPTH (channel d). cDNA was synthesised using the method of Efstratiadis *et al.*⁸. The reactions

Characterisation of protein synthesised in the linked system

We took advantage of the detailed characterisation of Pre-ProPTH (refs 4–6) to investigate the structure of the protein synthesised from cDNA. Immunoprecipitation of the products from the linked transcription-translation reaction with guinea pig antiserum to PTH and rabbit anti-guinea pig serum produced a polypeptide that co-migrated on sodium dodecyl sulphate (SDS)-urea polyacrylamide gels with authentic, mRNA-directed Pre-ProPTH (Fig. 2). Moreover, no ^{35}S -methionine-labelled peptide comigrated with Pre-ProPTH in immunoprecipitates prepared from cell-free reactions lacking either cDNA or RNA polymerase. The cDNA-directed product was not precipitated when treated with non-immune serum and rabbit anti-guinea pig serum or when bovine PTH (35 $\mu\text{g ml}^{-1}$) was included before the addition of anti-PTH antiserum and rabbit anti-guinea pig serum. The specificity of the immunological studies was strengthened further by control experiments in which anti-PTH antiserum and rabbit anti-guinea pig serum did not precipitate any of the numerous ^{35}S -methionine polypeptides synthesised in the linked system in response to SV40 DNA, form I (ref. 12). Thus, our cDNA-directed product contains antigenic determinants that are present in PTH.

Methionine is present at positions 1, 2, 7, 11 and 14 in the amino-terminal region of Pre-ProPTH (ref. 4). We therefore used Edman degradation to determine the location

of the methionines in the structure of the cDNA-directed product that was labelled with ^{35}S -methionine (Fig. 3). ^{35}S -methionine was released during the degradations at cycles 1, 2, 7, 11 and 14, a pattern identical to that found in a similar sequence analysis of mRNA-directed Pre-ProPTH. Thus, sequence studies, immunological data, and electrophoretic analysis indicate that the structure of the cDNA-directed product is very similar, if not identical, to the structure of Pre-ProPTH. We conclude that the cDNA that we have synthesised contains a faithful representation of the structural information for Pre-ProPTH and can express this information in the linked, transcription-translation system.

Discussion

The linked transcription-translation system provides an important method for assessing the fidelity and completeness of the cDNA products of the reverse transcription of mRNA. Furthermore, the method is independent of hybridisation and sizing tests. Figure 4 summarises the reactions required to synthesise Pre-ProPTH in the linked transcription-translation system. The synthesis of cDNA is presumed to begin at or near the 3'-terminus of the mRNA with an oligo-dT primer and clearly extends to the nucleotides encoding the N-terminal methionine of Pre-ProPTH. Therefore, the cDNA must include the complement of any untranslated region at the 3' end of the mRNA (region C in Fig. 4). It must also span the region coding

Table 1 cDNA-directed RNA and protein synthesis in the linked transcription-translation system

Experimental conditions	Trichloroacetic-acid insoluble radioactivity	
	RNA- ³ H c.p.m.	Protein- ³⁵ S c.p.m. × 10 ⁻³
Experiment 1		
<i>a</i> No nucleic acid	2,320	226
<i>b</i> No RNA polymerase	2,060	266
<i>c</i> cDNA-directed product	10,820	1,010
<i>d</i> mRNA-directed product		538
Experiment 2		
<i>e</i> cDNA-directed product		599
<i>f</i> DNase (0.1 mg ml ⁻¹) included along with cDNA		240
<i>g</i> No RNA polymerase		240
<i>h</i> No nucleic acid added		202
<i>i</i> mRNA (0.2 µg) added at time of transcription		1,447
<i>j</i> As (<i>i</i>) plus DNase (0.1 mg ml ⁻¹)		1,231

Experimental conditions detailed in Fig. 1 legend. RNA synthesis was measured using ³H-UTP (0.1 Ci mmol⁻¹). 0.5 µl of the 10 µl transcription reaction was counted before the addition of translation reagents. The values for radioactivity refer to the total (10 µl) in the reaction mixture. The RNA radioactivity in reactions (*b*) and (*c*) was derived by subtracting the known amount of ³H-cDNA (8,200 c.p.m.) added to each reaction from the total radioactivity in the reactions (10,260 and 19,020 respectively). ³⁵S-methionine (460 Ci mmol⁻¹) was used in the translation reactions. 1 µl of the 50 µl translation reaction was measured. The radioactivity in the Table refers to the total 50 µl. The reactions (*a*)–(*h*) correspond to reactions (*a*)–(*h*) in Fig. 1.

Fig. 2 Indirect immunoprecipitation of Pre-ProPTH. Approximately 100,000 c.p.m. of ³⁵S-methionine-labelled protein from each reaction were added to 200 µl 0.05 M veronal buffer (pH 8.5), 1% foetal bovine serum. Guinea pig anti-PTH serum (GP1) (ref. 26), diluted to a final concentration of 1:1000, was added to each tube except (*d*). After 24 h at 4 °C, 50 µl of rabbit anti-serum to guinea pig globulin (Arnel) were added to each tube, and the tubes were incubated at 4 °C for an additional 24 h. The resulting precipitates were collected by centrifugation at 1200g for 30 min, washed twice with 2 ml of 0.15 M NaCl, 0.02 M Tris-HCl (pH 7.5) and dried. The proteins were analysed by electrophoresis on an SDS-15–20% polyacrylamide slab gel²⁷. The gel was fluorographed²⁸ (channel *f* for 1 d, all the rest for 10 d) at -70 °C using Kodak SB-5 film. Immunoprecipitates of the following reactions are displayed: channel *a*, no cDNA or RNA polymerase added; *b*, cDNA added without RNA polymerase; *c*, cDNA and RNA polymerase added and non-radioactive PTH (35 µg ml⁻¹ during immune precipitation) added along with anti-PTH serum; *d*, cDNA and RNA polymerase added and non-immune serum substituted for anti-PTH serum at the same dilution; *e*, cDNA and RNA polymerase added; *f*, 0.08 µg mRNA added directly to wheat-germ translation reaction; *g*, 0.1 µg SV40 DNA (form I), and RNA polymerase added; *h*, same as *g* but non-radioactive PTH (35 µg ml⁻¹ during immune precipitation) added along with anti-PTH antiserum. O, origin; BPB, bromophenol blue front.

for Pre-ProPTH (region B), and reach at least the initiator codon at the 5' end of the mRNA.

If region A contains sequences necessary for message

Fig. 3 Sequence analyses of *a*, ³⁵S-methionine-labelled Pre-ProPTH synthesised in response to parathyroid mRNA in the wheat-germ cell-free system and *b*, the major ³⁵S-methionine-labelled protein synthesised in the linked transcription-translation system in response to parathyroid cDNA. The Pre-ProPTH (*a*) was isolated by electrophoresis on an SDS-urea polyacrylamide gel²⁴ and the cDNA-directed protein by indirect immunoprecipitation with an antiserum to PTH. The radiolabelled proteins were subjected to automated Edman degradation (Beckman 890 sequencer) in the presence of 2 mg of apomyoglobin added as carrier. Aliquots of one-third of the total radioactivity released at each cycle of degradation were assayed directly for radioactivity as the butyl chloride extract. The identity of the radioactive amino acids was confirmed by chromatography of the remainder of each fraction on thin layer plates as described previously³. The continuous curved line represents the theoretical recoveries of methionine on each cycle based on the efficiency of degradation³.

activity in the linked transcription-translation system, then our cDNA must extend into region A. Unfortunately, there is no firm information about the absolute requirement for

this region in our experiments. Shine and Dalgarno¹³ have shown that prokaryotic mRNA's contain sequences that are complementary to a sequence on 16S ribosomal RNA. Binding studies¹⁴ using mRNA from R17 bacteriophage and *Escherichia coli* ribosomes suggest that this sequence is functionally important. Ptashne *et al.*¹⁵ have suggested, however, that ribosomal-binding sequences on mRNA may not be absolutely required for mRNA activity. They have demonstrated that the bacteriophage λ repressor mRNA transcribed from the promoter p_{RM} does not require a 5'-terminal extension beyond the initiator AUG-codon for translation, albeit inefficient translation, *in vivo*. Furthermore, the functional importance of ribosomal-binding sequences¹⁶ or other sequences 5'-proximal to the initiator nucleotides has not been determined for eukaryotic messages. Thus we cannot be certain about the completeness of the polynucleotide sequence of our cDNA in region A.

Fig. 4 Diagram of cDNA synthesis and synthesis of Pre-ProPTH in the linked *in vitro* transcription-translation system. Horizontal solid lines indicate sequences necessarily synthesised in the functioning linked system. Dotted lines indicate sequences that may have been synthesised. The N-terminal methionines of the Pre-ProPTH synthesised in the linked system are indicated. Horizontal arrows under cDNA, RNA, and Protein denote the direction of synthesis of these molecules.

Our demonstration that RNA synthesised in the linked transcription-translation system is accurately translated into Pre-ProPTH raises interesting questions regarding the role of the 7-methyl guanosine terminal in the activity of parathyroid mRNA. Kemper¹⁷ has reported that treatment of Pre-ProPTH mRNA sequentially with periodate and aniline inactivates the message almost completely. Control studies suggested that periodate and aniline were effective at least partly because they removed 5'-terminal 7-methyl guanosine¹⁷. These studies of Kemper and more recent data from Rose and Lodish¹⁸ demonstrate that periodate and aniline treatment can inactivate messages by producing alterations in the mRNA other than removal of 7-methyl guanosine. Therefore, whether or not the Pre-ProPTH mRNA absolutely requires a 7-methyl guanosine terminus in order to be translated is unresolved. In our studies either 'uncapped' RNA is translated or a 7-methyl guanosine cap is added to the RNA by the linked transcription-translation system. Analysis of the newly-synthesised RNA should resolve this issue.

We are as yet uncertain as to whether or not our functional cDNA is single or double-stranded. Using conditions similar to those that we have followed, Efstratiadis *et al.*⁸ found that only 9.2% of their globin cDNA was double stranded, as defined by resistance to the S1 nuclease, which is specific for single-stranded nucleic acid. This fraction became even smaller (4.4%) when actinomycin D

was added during reverse transcription. We did not include actinomycin in our reaction mixture during synthesis of cDNA and cannot be sure how much of our DNA is double-stranded. Conceivably, even a small amount of double-stranded DNA could be responsible for all meaningful transcription. Further studies using actinomycin D and techniques for separating single and double-stranded DNA are underway.

The methodology described here should be particularly useful for investigators attempting to introduce functional DNA into bacteria²⁰⁻²². At each stage of synthesis and modification of the DNA, the DNA can be monitored to assure that the nucleic acid retains sufficient information to code for appropriate proteins. After the vector has been successfully introduced into bacteria, restriction fragments of the recombinant DNA can be similarly assayed. If the particular protein of interest is not synthesised by the bacteria, the linked system should allow the detection of potentially functional sequences not properly transcribed by the bacteria. An additional strength of this methodology is that the cDNA employed in the studies need not be pure. Crude cDNA mixtures, which can later be purified by cloning, can be shown to contain the structural information for the proteins of interest.

The parathyroid cDNA is a suitable starting material for nucleotide sequence analysis²³. These data should be especially interesting in regions A and C of Fig. 4. Further, the synthesis of double-stranded parathyroid DNA should provide a substrate for detailed restriction endonuclease analysis. The ligation of specific DNA restriction fragments could generate DNA molecules with characteristic deletions and insertions. The behaviour of these modified DNA's in the linked transcription-translation system should allow a detailed analysis of the function of specific untranslated nucleotide sequences. Similar experiments can be carried out in the coding region B to create modified versions of PTH whose activities could be assayed in biological systems.

Mechanism of acid protease catalysis based on the crystal structure of penicillopepsin

Michael N. G. James, I-Nan Hsu & Louis T. J. Delbaere

MRC Group on Protein Structure and Function, Department of Biochemistry, University of Alberta, Edmonton, Alberta, T6G 2H7, Canada

A proposed mechanism for the catalytic hydrolysis of peptide bonds by acid proteases is similar in many respects to the Zn-carbonyl mechanism previously derived for carboxypeptidase A. In the acid proteases the electrophilic component is the proton shared by Asp-32 and Asp-215; Tyr-75 donates its proton to the amide nitrogen of the scissile bond and an OH⁻ ion from a water molecule bound between the carboxyl group of Asp-32 and the substrate attacks the carbonyl carbon atom.

ACID proteases catalyse the hydrolysis of peptide bonds at acidic pH values. The solutions of high resolution structures of three of these enzymes isolated from diverse microbial sources have been reported^{1,2}. These crystal structures will be of fundamental importance in elucidating the catalytic mechanism of acid proteases. The electron density map of penicillopepsin¹ is exceptionally well defined and the region of the active site is unambiguous in its interpretation. In addition, this is the only acid protease for which both the primary structure and crystal structure have been determined. We are therefore in a position to propose a mechanism based on structural information and previously documented chemical data.

Our primary concern in the present discussion is the bond-breaking step of polypeptide substrate hydrolysis by acid proteases. Further studies with substrate analogues, inhibitors and virtual substrates will add to our present interpretation of the catalytic mechanism and should provide the details of the enzyme-substrate interactions of elongated substrate peptide chains.

The history of studies of the catalytic mechanism has been most recently reviewed by Fruton³. In that article a number of proposals for future research were also made. We present here additional data which could help in the interpretation of those experiments. Moreover, neither a covalent amino-enzyme nor a covalent acyl-enzyme intermediate is required by the mechanism described here. The existence of these covalent intermediates was essential to many of the previous hypotheses but the intermediates have not been detected.

Crystal data

Penicillopepsin crystallises in the monoclinic system (space group, C2, with unit cell dimensions $a = 97.38(8)$, $b = 46.62(3)$, $c = 65.39(6)$ Å and $\beta = 115.4(3)^\circ$) from a 9 mg ml⁻¹ solution of the enzyme and 2.5 M Li₂SO₄, 0.1 M sodium acetate at pH 4.4. The low-resolution crystal structure at 6 Å showed that the molecule was decidedly asymmetric with dimensions

Fig. 1 *a*, Stereoscopic representation of the penicillopepsin α -carbon model. The arrow is shown in the extended substrate binding cleft which divides the molecule into two approximately equal halves (the N-terminal domain is to the left, the C-terminal domain to the right). Asp-32 (in the N-terminal domain) and Asp-215 (in the C-terminal domain) have their α -carbon positions in a dark colour. *b*, Stereoscopic drawing (from the program ORTEP of Dr Carroll Johnson) of the polypeptide chain. The view is from the top of that shown in (*a*). Every tenth α -carbon atom has been assigned a number corresponding to the sequence given in ref. 1. The active site region is that region shown with black connectivity; Asp-32 and Asp-215 are labelled.

$65 \times 49 \times 39 \text{ \AA}$ (ref. 4). Intensity data to $2.8 \text{ \AA}$ resolution (6,700 unique reflections) were obtained from a single crystal of native penicillopepsin and each of the eight heavy-atom derivatives used for determining phases by the method of multiple isomorphous replacement (MIR). The data collection protocol is discussed in more detail in refs 5 and 6 and the statistics regarding the phase determination are given in ref. 1. The overall mean figure of merit of the 6,127 statistically significant reflections was 0.90 (for zero error in phase angle this index has a value of 1.0). Observed native structure factor amplitudes and the 'best' phases⁷ were used to compute the electron density function of the penicillopepsin molecule. This map was interpreted using the partial sequence data⁸ for 16 fragments of penicillopepsin. In this way, it was possible to correlate the majority of the 322 residues in the polypeptide chain with the sequence data. Eight amino acid residues, however, were assigned from electron density distribution alone¹.

Structure and function

Figure 1 shows two different representations of the α -carbon model of penicillopepsin. A deep cleft separates the two lobes of the molecule and the active site is located within this cleft. A more detailed description of the polypeptide chain conformation is given in ref. 1. The positions of Asp-32 and Asp-215 are marked in the figures as an aid to orientation. The extensive hydrophobic core (in the shape of a croissant) appears as a relatively 'empty' region surrounded by the 18-strand mixed β -sheet, the major structural determinant of penicillopepsin. This hydrophobic core is highly ordered in the electron density map and the aromatic and aliphatic side chains are absolutely unambiguous in their assignment.

1,2-Epoxy-3-(*p*-nitrophenoxy) propane binding to penicillopepsin

The reagent 1,2-epoxy-3-(*p*-nitrophenoxy) propane (EPNP) is a specific inhibitor of acid proteases and has been used to identify the carboxylate group of Asp-32 at the active site⁹. Direct proof that Asp-32 and Asp-215 are present in the active site of penicillopepsin comes from the following experiment. A single crystal of penicillopepsin was soaked for 15 d in a saturated solution of EPNP in standard buffer at pH 4.4. The $2.8\text{-\AA}$ diffraction intensity data were collected from this crystal and a difference electron density map was computed from the amplitudes ($|F_{\text{EPNP}}| - |F_p|$) and the MIR phases (α_p). This map had significant density in only two regions. One region corresponds to what we interpret as a non-covalently-bound EPNP molecule in a solvent cavity between two protein molecules in the vicinity of residues 27–29 and 116–117. The second and more interesting region involves residues in the active site. This portion of the difference map is shown in Fig. 2. The positive values of difference density, indicated by solid lines, show that two molecules of EPNP have reacted covalently with penicillopepsin, one with the carboxyl group of Asp-32, the other with the carboxyl group of Asp-215. In addition, Fig. 2

shows a concomitant pronounced conformational change of Tyr-75 in which the side chain phenoxyl group moves from a position where it was hydrogen-bonded to Trp-39 (an invariant residue in penicillopepsin and pepsin) to one in which it lies coplanar with the *p*-nitrophenoxy moiety of the EPNP molecule bound to Asp-32.

Room temperature studies of Chen and Tang¹⁰ on the inhibition of porcine pepsin with EPNP resulted in two peptides which had covalently bound EPNP; one with the sequence Asp(EPNP)-Thr-Gly-Ser-Ser-Asn (residues 32–37) and the other with sequence Ile-Val-Asp(EPNP) (residues 213–215). A similar experiment at 4°C by Hartsuck and Tang⁹ resulted in only one EPNP reactive peptide which corresponded to the Asp-32 sequence. Chen and Tang¹⁰, perhaps in view of the low temperature results, chose to assign the EPNP reactive site only to Asp-32. Their observations and our present knowledge of the sequence are in good agreement with the fact that both Asp-32 and Asp-215 have reacted with EPNP in penicillopepsin crystals at room temperature.

Although it is possible to accommodate two EPNP molecules simultaneously in this active site region of penicillopepsin, it could also be that the binding of one EPNP molecule to either of Asp-32 or Asp-215 would preclude the binding of the second EPNP molecule and that we are actually observing statistical disorder in the crystals. This is unlikely, as the two peaks of electron density (Fig. 2) are of approximately equal size, and the interplanar separation of the *p*-nitrophenoxy moieties is of the order of $3.5 \text{ \AA}$, a reasonable value for aromatic rings. The residues of penicillopepsin that are close to the EPNP molecule bound to Asp-215 are those residues that are likely to be responsible for binding natural peptide substrates in the S_1 site of penicillopepsin. These residues are Leu-222, Thr-218, Ile-301 and a segment of the hairpin loop from Asn-290 to Ile-297 (see Fig. 1).

The conformational change observed for Tyr-75 is of particular interest because of the analogy of this movement with that observed in substrate binding with carboxypeptidase A_a (refs 11, 12). Tyr-75 is located on a hairpin loop (β -bend) which involves residues 70–83 (see Fig. 1). In the penicillopepsin electron density map, the density corresponding to this 'flap' is very well defined because this region represents a close intermolecular contact between two penicillopepsin molecules across a twofold symmetry axis in the crystals. There is a third strand which anchors the flap into a three stranded antiparallel β -sheet. These strands do not form part of the major 18-stranded β -sheet, but they are made up of stretches of β -chain conformation from residues, 70–77; 78–83; 105–108. Although the conformational changes induced on EPNP binding involve only Tyr-75 (rotation around the C_α - C_β bond), it is probable that this whole 'flap' region undergoes a major conformational change to accommodate the binding of longer substrate molecules. This would be the reason for the CD spectral changes observed when binding certain activators to penicillopepsin¹³.

Fig. 2 Stereoscopic photograph of the difference electron density map of the covalent inhibitor EPNP (see text). Positive values of difference density are represented as solid contours, negative values with dashed contours. The two EPNP molecules bind to the carboxyl groups of Asp-32 and Asp-215 and the *p*-nitrophenoxy moieties are coplanar and point towards the bottom of the photograph. Since this is a difference map the electron density of the carboxyl groups is not seen, but lies approximately where the side chains are designated (see Fig. 3a). The conformational movement of Tyr-75 is seen to the right of and below the positive density of the EPNP molecule bonded to Asp-32.

Fig. 3 *a*, Electron density map of penicillopepsin in the region of the active site. Side chains of the amino acids discussed in text have been labelled with the numbering given in ref 1. *b*, Schematic interpretation of the electron density map shown in 3*a* showing the disposition and hydrogen-bond interactions between the several groups in the region of the active site (portions with black connectivity in Fig. 1*b*). The bound water molecules are labelled W(1) W(2) and W(3).

A final point regarding the EPNP studies concerns the difference of the nature of the covalent penicillopepsin-EPNP complexes with Asp-32 and Asp-215. The mechanism of ring opening of 1,2-epoxides in acid solution favours products in which the nucleophile attacks the 2 position of the propane moiety¹⁴. The electron density associated with the EPNP molecule bonded to the carboxyl group of Asp-215 is consistent with this mechanism as there is difference density on either side of the carboxyl group. But, the difference electron density of the EPNP molecule which has reacted with Asp-32 clearly terminates at that group on the enzyme and the complex is Asp-32 (EPNP) with the carboxyl group bonded to the 1 position of the propane moiety. This fact indicates that the carboxyl group of Asp-32 is inaccessible for the formation of covalent intermediates with peptide substrates without major conformational changes in the enzyme's tertiary structure. A negative peak on the difference map in the region between the two carboxyl groups of Asp-32 and Asp-215 shows that the hydrogen-bonded complex of these two groups in the native enzyme structure has been disrupted by their reaction with EPNP.

Disposition of groups in the active site of penicillopepsin

Before considering the catalytic mechanism of acid proteases, we feel it is important to emphasise further that the two carboxyl groups located in the active site are relatively inaccessible to substrate molecules, and that most of the region is inflexible to gross conformational changes. A carboxylate anion (Asp-32) and a protonated carboxyl group (Asp-215) have been implicated in the catalytic mechanism of acid proteases (ref. 3 and references cited therein). The sections of the electron density map which contain these groups are shown in Fig. 3*a*. Figure 3*b* is a schematic representation of the corresponding part of the molecule. It can be seen that the carboxyl group of Asp-32 is in an unusually tight hydrogen-bonded environment reminiscent of the hydrogen-bonded environment of Asp-102 of the serine

proteases¹⁵. The contacts that are made to the carboxyl group of Asp-32 include (1) the carboxyl group of Asp-215, (2) the O⁻ of Ser-35, (3) the main chain N-H of Gly-217 and (4) a bound water molecule W(1). Although not seen in Fig. 3, the main chain from Asp-32 to Gly-34 traverses directly above (towards the viewer) the carboxyl group of Asp-32 and makes several close contacts with this moiety.

The carboxyl group of Asp-215 is more exposed to solvent than is the carboxyl group of Asp-32. The side chain of Thr-218 is located to the left and below (away from the viewer in Fig. 3*a*) the COOH group of Asp-215 but no direct hydrogen bonding exists between these two side chains. Two water molecules, W(2) and W(3), are within hydrogen-bonding distance of Asp-215. The side chain Ile-213 is seen above and to the left of Asp-215 and in conjunction with the side chains of Phe-189 and Tyr-299 probably forms the S₁' hydrophobic binding site in penicillopepsin¹⁶. These residues correspond to Ile-213, Tyr-189 and Leu-299 respectively, in pepsin¹⁷.

There are other residues in the neighbourhood of the two active site aspartic acid groups. The peptide bond from Thr-216 to Gly-217 lies between the two carboxyl groups of Asp-32 and Asp-304. The carboxyl group of Asp-304 (Fig. 3), deeply buried in the hydrophobic core of the molecule, makes a hydrogen-bonded contact with the main chain C=O of Thr-216. To the left of Asp-304 there is an ion-pair, formed by Lys-308 and Asp-11, which has neighbouring residues Tyr-14 and His-157 to its right and left respectively. Tyr-14 is also buried in the hydrophobic core and the hydroxyl group lies within 3.2 Å of Asp-304 and the ion-pair Lys-308 to Asp-11. All of the above mentioned residues with the exception of His-157 are conserved in the porcine pepsin sequence^{1,17}.

In addition to these side chain interactions it is important to consider the polypeptide chain conformation in the vicinity of the active site aspartic acid residues. Both residues are in regions of chain that show a high degree of not only primary structural homology but also tertiary structural homology¹. The chain from Phe-31 to Ser-35 adopts a similar conformation

Fig. 4 Proposed tautomeric form of the peptide bond between Thr-216 and Gly-217 which could result from conformational changes induced on the binding of extended substrate peptides to penicillopepsin. The net effect is to enhance the electrophilic character of the proton between Asp-215 and Asp-32.

to the segment of chain from Ala-214 to Thr-218. (There is in fact much more extensive tertiary structural homology between the two lobes of penicillopepsin, but it is not pertinent to the discussion here and will be considered in a subsequent publication). Asp-32 is in strand c (strand nomenclature for penicillopepsin and the corresponding residue numbers within strands are given in ref. 1), with nearest neighbours strand h (running parallel to c) and strand m (anti-parallel to c) which contains Asp-215. In addition to strand c, strand m (containing Asp-215) has a parallel strand p which is its other nearest neighbour strand. These main chain conformations and the fact that the strands are in an extensive mixed β sheet which has a pronounced hydrophobic side, lead one to the inference that the active site region is conformationally rigid and that movement of the two lobes relative to one another would not make the active site much more accessible to substrate. In support of this, it has been observed that pepsin and penicillopepsin retain partial catalytic activity in 8 M urea (T. Hofmann, unpublished).

The immediate surroundings of the two active site carboxy groups are consistent with the observations that Asp-32 has a low pK_a and Asp-215 has a high pK_a , and the latter would be predominantly protonated at pH values from 2 to 4. As this proton is shared between these two carboxyl groups, however, there would be little driving force for it to act in the role of facilitated proton transfer to the substrate carbonyl oxygen atom in the manner suggested by Knowles¹⁸. The presence of the carboxyl group of Asp-304 adjacent to the peptide bond between Thr-216 and Gly-217 offers a charge relay system which is the major factor giving this shared proton an electrophilic character. Enhanced electrophilicity of this proton may be achieved by the mechanism depicted schematically in Fig. 4. Asp-11 is at the extremity of a hairpin loop (strands a and b, ref. 1) in the central portion of the large mixed β -sheet region that would be involved with the binding of an extended substrate molecule. A relatively minor conformational change of this loop would disrupt the Asp-11 to Lys-308 ion pair, and at least in penicillopepsin, Asp-11 could form an alternative ion pair with His-157 which is on the surface of the enzyme and is protonated at pH values < 5 . This induced conformational change would leave an almost completely buried positive charge of Lys-308 in the hydrophobic interior. This energetically unfavourable situation could be relieved by a subsequent conformational change in which the carboxyl-group of Asp-304 protonates the main chain carbonyl oxygen atom of Thr-216 and rotates by $\sim 120^\circ$ about the $C_\alpha-C_\beta$ bond to form an internally buried ion-pair with Lys-308. The protonation of the peptide bond between Thr-216 and Gly-217 would then produce

the tautomer as shown in the diagrammatic sketch in Fig. 4. Support for this proposal comes also from chemical studies of Kitson and Knowles¹⁹ and Huang and Tang²⁰ in which it was observed that chemical modification of arginine residues of pepsin resulted in a loss of catalytic activity. Chemical modification of Lys residues of penicillopepsin results in a similar loss of activity (T. Hofmann, unpublished). As the only basic residue that is in common between porcine pepsin and penicillopepsin¹ is at position 308 we suggest that Arg-308 is the modified residue in porcine pepsin.

These conformational changes involving Asp-11, Lys-308 and Asp-304 represent an extreme case in which a very strong acid, the protonated peptide bond between Thr-216 and Gly-217, is formed. We do not suggest that this extreme conformational change is ever reached, however. A partial contribution towards the tautomer shown in Fig. 4 would also result in enhanced electrophilic character of the proton which is bound between the two carboxyl groups Asp-32 and Asp-215, rendering this proton more labile than one would expect in its shared state as seen in the penicillopepsin structure. The degree of electrophilic character of the proton would then be a function of the relative contributions of these two tautomeric forms of the Thr-216 to Gly-217 peptide bond.

Our structural studies have shown that penicillopepsin has an extended substrate binding groove¹. A protein conformational change is known to occur when certain tripeptide activators (Leu-Gly-Leu) bind in a region near Trp-39, Trp-71 and Tyr-75 (ref. 13). Transpeptidation products isolated from reaction mixtures in which the activators are present indicate that this binding region (secondary A site as defined by Takahashi and Hofmann¹⁸) is the N-terminal region of bound substrate, that is, P_1-P_4 . In addition, Fruton has shown that increased substrate chain length in the N-terminal direction from the scissile bond enhances k_{cat} with little difference in substrate binding affinity³. These effects may now be explained by the increased electrophilic character of the proton between the two carboxyl groups of Asp-32 and Asp-215.

Towards a catalytic mechanism for acid proteases

The acyl-enzyme mechanism for serine proteases is well established¹⁸ and the postulated tetrahedral intermediate in that pathway has subsequently been observed in crystalline trypsin-trypsin inhibitor complexes^{21,22}. Catalytic mechanisms for the thiol proteases²³ and metalloproteases¹³ have also been advanced and the proponents of these mechanisms have drawn heavily on the results of crystal structural studies. In the most recent review article on acid protease mechanisms³, Fruton states at the outset "that speculations about the catalytic mechanism of pepsin have been limited by lack of information about the three-dimensional structure of its active site . . .". The electron density map of penicillopepsin at 2.8-Å resolution¹ provides the missing details of the active site geometry and the following proposed mechanism is based on the structural results and on chemical and kinetic studies done with synthetic substrates of acid proteases.

The description of the active site geometry of penicillopepsin in the previous section, by no means exhaustive, was intended to convey two major points: (1) that the β -carboxyl group of Asp-32 is too buried for this group to act as an attacking nucleophile directly, and (2) that the sum of the interactions of the groups in the active site and the conformations of the main polypeptide chains prohibit large conformational changes in this region. A conformational change involving the extensive anti-parallel β sheet which contains Tyr-75, as discussed above, is possible however, and probably accounts for the conformational changes observed on binding certain peptide activators. It is also unlikely that the carboxyl group of Asp-215 acts as an attacking nucleophile even though it is partially exposed to solvent, because it is the carboxyl group with the higher apparent pK_a of 4.7 (ref. 18). How then is one to accommodate peptide bond catalysis by acid proteases?

Fig. 5 Proposed general base catalytic mechanism of the acid proteases. *a*, Schematic drawing of the productive binding mode for substrate RCONHR' in the active site of penicillopepsin. The conformational change of the 'flap' region brings Tyr-75 to a position from which it can protonate the amide nitrogen of the scissile bond. Asp-32 attacks the carbon atom of the polarised $C^{\delta+} \cdots O^{\delta-} \cdots H^{\delta+}$ system through the bound water molecule W(1). Transpeptidation through acyl or aminic transfer is a function of the relative affinity of the enzyme for the acyl or amino fragment shown in *b*.

The scheme that we propose is shown in Fig. 5 which contains the essential details of the active site (shown more extensively in Fig. 3). It also includes the scissile peptide bond of a hypothetical substrate RCONHR'. The structure of the binding region, as observed in the Kendrew model of penicillopepsin, is compatible with that orientation of an X-Phe-Phe-Y type substrate (the Phe-Phe bond being cleaved). Side chain interactions of substrate with enzyme have been omitted from Fig. 5 to enhance clarity, but are essentially as described in the previous sections.

The formation of the Michaelis complex is accompanied by a conformational change of the flap region (residues 74–80) which has to open outwards to admit the substrate into the extended substrate binding cleft. We have pointed out an approximation to this change in the EPNP binding experiment, where it was limited to the movement of Tyr-75 by the crystal packing of molecules of penicillopepsin. Substrate binding also displaces water molecules W(2) and W(3), whereas W(1) can remain in its original position. It now lies between the substrate (as postulated) and the carboxyl group of Asp-32. With the substrate bound, the flap can return and in so doing, the phenolic OH of Tyr-75 comes close to the amide of the susceptible peptide bond. The productive binding mode is now complete as depicted in Fig. 5*a*.

It is useful to point out the analogy of this binding mode to the substrate orientation found for glycytyrosine in the carboxypeptidase A study done by Lipscomb and co-workers^{11,12}. In our case, Tyr-75 is in a position to protonate the amide nitrogen atom of the peptide bond (Fig. 5*a*). This function is carried out by Tyr-248 in carboxypeptidase A after a similar conformational change of the phenolic group upon substrate binding. The electrophilic component of the carboxypeptidase mechanism is ascribed to the Lewis acid, Zn^{2+} in the Zn-carbonyl mechanism. Polarisation of the carbonyl bond in the case of acid proteases is accomplished by the proton shared between the two active site carboxyl groups. We propose that the electrophilicity of this proton is a function of the nature of the substrate, and could be enhanced by specific enzyme-substrate interactions as described in the previous section.

Finally, the Zn-carbonyl mechanism for carboxypeptidase A postulates either a direct nucleophilic attack of Glu-270 on the polarised carbonyl carbon of the peptide bond or a general base attack through a bound water molecule. The analogous residue to Glu-270 of carboxypeptidase A is the carboxylate of Asp-32 of the acid proteases. Carboxypeptidase A has a pH optimum close to 7.5 where the Glu-270 side chain would have a carboxylate anion. The special requirement of acid proteases in having an ionised carboxylate at very low pH values are met by the most unusual environment of the Asp-32 side chain. We propose that attack of the polarised carbonyl carbon atom of the scissile peptide bond occurs through the activated water molecule W(1) rather than by direct nucleophilic attack by the

$\beta\text{-COO}^-$ of Asp-32 (Fig. 5*a*). Thus we prefer this general base mechanism of hydrolysis without the involvement of either an anhydride or an amino-enzyme intermediate.

A major stumbling block in the various other proposed mechanisms of acid proteases, as reviewed by Fruton³, has been the inability of workers to trap either of the covalent intermediates (acyl-enzyme or amino-enzyme). Our proposal obviates this problem and postulates a ternary complex of enzyme, acyl-fragment and amino-fragment after cleavage of the susceptible peptide bond. The order of release of products is determined by the relative affinity of the acyl or amino moiety to their respective binding sites²⁴.

Transpeptidation is a phenomenon peculiar to the acid proteases and it has only been observed to proceed to any significant degree at pH values greater than 4.0. Our mechanism is also compatible with the transpeptidation phenomenon. The products resulting from hydrolysis of the peptide bond are most likely the carboxylate ($R\text{-COO}^-$) and the protonated amino group (NH_3^+-R'). Transfer of the proton from the carboxyl group to the amino group would occur readily and the positively charged amino group could be stabilised by the phenoxide ion of Tyr-75 (Fig. 5*b*). As an example, consider the work of Newmark and Knowles²⁴ on pepsin, in which they studied the transpeptidation products from the peptide $^{14}\text{C}\text{-Leu-Tyr-}^3\text{H}\text{-Leu}$. Approximately 80% of the resulting Leu-Leu is $^{14}\text{C}\text{-Leu-}^{14}\text{C}\text{-Leu}$; the remainder is $^3\text{H}\text{-Leu-}^3\text{H}\text{-Leu}$ with none of the mixed radiolabelled product. This tripeptide binds initially such that the N-terminal Leu-Tyr bond is cleaved. Exchange of Tyr-Leu with a second Leu-Tyr-Leu is more facile than the exchange of the bound N-terminal $^{14}\text{C}\text{-Leu}$ product from the first hydrolysis. Transpeptidation would occur through the microscopic reversibility of the mechanism shown in Fig. 5, yielding the Leu-Leu-Tyr-Leu which is subsequently cleaved by a second hydrolytic step to give $^{14}\text{C}\text{-Leu-}^{14}\text{C}\text{-Leu}$. Fruton³ has pointed out that at pH values at which transpeptidation occurs (>4.0) the equilibrium constant for the reaction: $\text{RCOO}^- + \text{H}_3\text{N}^+ - \text{R}' \rightleftharpoons \text{RCONHR}' + \text{H}_2\text{O}$ is 1 and reversal of the hydrolytic step is equally probable. But, at pH values close to the optimum pH of pepsin ($\text{pH} \sim 2$) one would expect the carboxyl of the acyl fragment to be protonated, thus precluding transpeptidation at low pH values.

Conclusions

The mechanism proposed here is consistent with the disposition of amino-acid groups at the active site of penicillopepsin and with various characteristics of acid protease hydrolysis. The electrophilic component of hydrolysis is the shared proton between Asp-32 and Asp-215 (ref. 18). The electrophilicity of this proton is a function of specific enzyme-substrate interactions and its variation is seen in the variation of k_{cat} with closely related substrates. We have not used hypotheses that require covalent acyl or amino intermediates because the

existence of these species has not been detected or conclusively proven. Whether or not transpeptidation proceeds through acyl or amino transfer (indeed both pathways have been observed in the same reaction mixture) is determined by the affinity of the amino or acyl moiety bound to the enzyme following the first hydrolytic step. Transpeptidation proceeds only at pH values where one has charged groups involved with the formation of the new peptide bond. Protonation of the carboxylate at low pH values precludes transpeptidation through this mechanism and favours hydrolysis.

Finally, another convincing argument in favour of this mechanism is the very close similarity to that one proposed by Lipscomb for carboxypeptidase A. It seems that these two enzymes have converged on a mechanism for the hydrolysis of peptide bonds which differs from that of the serine protease mechanism. The specific requirement of catalytic activity in strongly acid media precludes the use of a Lewis acid such as Zn^{2+} . The acid proteases have instead developed a bond-polarising system with a bound proton and a charge-relay system which influences the electrophilicity of this proton. Tyr-75 clearly is very similar to Tyr-248 of carboxypeptidase both in its function of transferring a proton to the amide nitrogen atom and the conformational change it undergoes on substrate binding. Both the metalloproteases^{12,25} and the acid proteases use an ionised carboxylate group to catalyse the conversion of the substrate carbonyl carbon to a transient tetrahedral intermediate which results in the cleaved peptide bond. The proposal here that acid proteases catalyse this step through general base attack through a bound water molecule ($W(1)$) lends support to this step being present as well in the carboxypeptidase A mechanism. It has been pointed out that the carboxypeptidase A mechanism resembles that of pepsin in several respects²⁶ and it is therefore gratifying to find that the structural features of penicillopepsin are consistent with such closely corresponding mechanisms of catalysis.

We thank Professors Jeremy Knowles and Theo Hofmann for helpful suggestions. This work was supported by MRC of Canada.

Note added in Proof: Completion of the building of the entire model of penicillopepsin has required the following revisions to the sequence reported in ref 1. (a) The molecule is made up of 323 residues. (b) The following residues are now interpreted as: 299 is Phe, 302 is Phe and 249–264 are tentatively assigned as: -Asx-Cys-Ser-Ser-Ser-Val-Pro-Asx-Phe-Ser-Val-Ser-Ile-Ser-Gly-Tyr-.

letters to nature

Intensity transitions in Cyg XR-1 observed at high energies from OSO 8

THE high energy X-ray source, Cygnus XR-1, exhibits a variable intensity between states which differ in flux at lower energies (typically 3 to 6 keV) by a factor of three (refs 1–5). Although the transitions between these 'high' and 'low' flux states occur at irregular intervals, the transition itself usually takes no more than one day in either direction. We report here an observation of such a transition at energies above 20 keV which shows that the spectrum of Cyg XR-1 exhibits the pivoting effect during intensity transitions expected from two-temperature accretion disk models of the X-ray emitting region^{6,7}.

Cyg XR-1 was observed with the high energy X-ray spectrometer on board the OSO-8 satellite from 11 to 19 November, 1975, and from 27 October to 15 November, 1976 (excluding the period from 1 November to 7 November, 1976). The CsI(Na) scintillation spectrometer is sensitive to radiation in the 20 keV to 3 MeV range. The detector is actively shielded and collimated to a 5-degree circular FWHM and offset by an angle of 5 degrees from the negative spin axis of the satellite. Further details of the instrument and its satellite environment are given by Dennis *et al.*⁸ Once every rotation period of the satellite (~10 s), any source on the detector's scanning circle will transit through its field of view. The data were analysed in the manner outlined by Dolan *et al.*⁹.

The raw counting rates during the 1975 observations in the interval 23 to 153 keV are shown in Fig. 1. Data are grouped in intervals of 0.55995 d, or a phase interval of one-tenth the period of the HDE 226868 binary system¹⁰. A decrease in counting rate of ~40% was observed to occur on 16 November, 1975, with the source remaining at a significantly lower counting rate after the transition than before it. Comparison with 3–6-keV proportional counter data taken by Holt *et al.*¹ and Serlemitsos (quoted in ref. 11) reveals a simultaneous rise in the lower energy counting rate. Boldt¹² distinguishes between 'transitions' and 'transient events'. In transient events, the 3–6-keV intensity fluctuates by a large amount from its previous value but returns to its original level within a few binary periods; in transitions, the flux remains at its new level for many binary periods. We cannot distinguish between these two possibilities with our observations, and shall refer to all large variations lasting more than a few days as transitions. It is apparent that we have observed for the second time at higher energies¹³ a transition between intensity states in Cyg XR-1.

Our observations for 1976 are shown in Fig. 2. The 23–153-keV intensity was higher than that observed in 1975, indicating that a reverse transition must have occurred between the two observations, in agreement with the report of such a transition in February 1976, by Holt *et al.*¹ The decrease observed by us to occur on 14 November 1976, probably does not correspond to a change in intensity state at low energies;

Fig. 1 The 23-153-keV counting rates observed from Cyg XR-1 in November 1975.

the 23-153-keV flux after the transition is still above that observed by us before the transition in 1975. Instead, it illustrates the large intrinsic variability present in the source even when in the 'low' state at lower X-ray energies. No 3 to 6 keV proportional counter data are available for comparison at the time of writing.

Typical spectra taken during periods of high and low intensity are shown in Fig. 3. The higher intensity spectrum, observed between phases 0.50 and 0.60 starting JD 2443092.505 (10 November 1976) is well fitted by a power law spectrum $dN/dE = C(E/E_0)^{-\alpha}$ photon $\text{cm}^{-2} \text{s}^{-1} \text{keV}^{-1}$ where $C = (1.8 \pm 0.1) \times 10^{-3}$ photon $\text{cm}^{-2} \text{s}^{-1} \text{keV}^{-1}$, $\alpha = 2.1 \pm 0.1$ and $E_0 = 73.6$ keV; the lower intensity spectrum, observed between phases 0.40 and 0.50 starting JD 2442733.583 (17 November 1975), is well fitted by a power law spectrum with $C = (1.0 \pm 0.2) \times 10^{-3}$ photon $\text{cm}^{-2} \text{s}^{-1} \text{keV}^{-1}$, $\alpha = 2.4 \pm 0.4$ and $E_0 = 57.2$ keV. The quoted uncertainties are 68% confidence intervals calculated according to the method outlined by Lampton *et al.*¹⁴. The anti-correlation between intensities at lower and higher energies indicates that the spectrum must pivot about a point between the two energy ranges. From the observations of Coe *et al.*¹³, this pivot point occurs at ~ 7 keV.

All individual spectra that we observe, measured over 0.6-d intervals, can be well fitted by a power law, although the

constant C varies from spectrum to spectrum. The resultant uncertainties in α obtained from fits in our limited energy range do not allow us to show a detailed correlation between observed spectral index and the 23-153-keV counting rate. All the 1976 data are at higher intensity than the 1975 data, however, and the 1976 data have a lower average value of α (2.05 ± 0.03) than the 1975 data ($\alpha = 2.39 \pm 0.04$), as would be expected from the discussion above. If these average spectra extend unchanged to lower energies, the 2-300-keV luminosity of the system is in fact greater when the source is more intense at lower energies (that is, the 'high' state at 3-6-keV is indeed the higher luminosity state of the system).

This pivoting behaviour (or 'see-saw' effect) is predicted to occur in models for which the X-ray emission is produced in a two-temperature accretion disk surrounding the secondary component of the binary system^{8,7}. In these models, the inner part of the accretion disk, ballooned up by radiation pressure, is geometrically thick but optically thin to higher energy X-rays. The high-energy radiation, predicted to have a power law spectrum, is produced from the lower energy X-ray or ultraviolet photons by inverse Compton scattering off relativistic electrons in this region of the disk. Basically, an increase in the lower energy photon flux 'cools off' the electrons by causing them to undergo more inverse Compton collisions, leading to a lower mean energy gained by the photons per scattering and, ultimately, to a lower flux of high energy photons. This anti-correlation between the fluxes in the two energy ranges would then be observed as the same type of pivoting of the spectrum that we detect in Cyg XR-1.

Transitions in Cyg XR-1 are observed to occur at irregular intervals, but seem to occupy much the same duration, about one day, regardless of direction of the transition or interval since the last transition¹⁻³. We note that not only the two transitions we observed (one of which may not be associated with a large change in the low energy flux) but also six of the seven other transitions in the intensity state of Cyg XR-1 reported in refs 1-5 commenced near periastron at phase 0.18 (ref. 10). It is tempting to speculate that transitions in the luminosity are linked to variations in the mass transfer rate from the primary to the accretion disk surrounding the secondary. Alme and Wilson¹⁵ have proposed a model of the system in which matter is transferred primarily by radiation-driven density waves generated in the atmosphere of the primary, which fills only about 85% of its Roche lobe. In such a model having the orbit eccentricity and period of the HDE 226868 system, nearly all the mass is transferred in an interval approximately 1 d long near periastron. As pointed out by Alme and Wilson, the period between mass transfer 'pulses'

Fig. 2 The 23-153-keV counting rates observed from Cyg XR-1 in October and November 1976. Note the difference in the scale of the ordinate from Fig. 1. Spacecraft pointing requirements prevented observations between 1 and 7 November.

Fig. 3 Typical spectra taken during a 3-6 keV 'low' state (crosses, above), and a 'high' state (diamonds, below). The straight lines are power law fits to the spectra; spectral parameters are given in the text. Error bars are ± 1 standard deviation in the flux. Individual channels in the original data have been grouped to improve statistics.

is not critically phase locked and the period between pulses is small compared with the characteristic disk transfer time. Hence, variations in the X-ray emission at this period would be difficult to detect if approximately the same amount of mass were transferred every pulse. If the primary, for some unspecified reason, suddenly changed drastically the amount of matter it transferred per pulse, however, the disk might then be expected to show a changed luminosity commencing near periastron.

A large increase in mass transferred per pulse would presumably increase the low energy photon flux in the outer regions of the disk. The high energy flux would then follow in an anti-correlated fashion, as discussed above. The difference between 'transitions' and 'transient events'¹² would then be related to whether the mass transferred in succeeding pulses was maintained at its new value or returned to its previous level. It will be interesting to see whether this correlation of commencement time with phase near periastron is borne out in future transitions.

On the association between a γ -ray burst and a radio pulse

ONE minute after the γ -ray burst of 16 August 1976, a radio event with ~ 30 s duration was recorded by three different instruments, a dipole array and a 10-m parabola at Medicina (Bologna), and a 10-m parabola at Trieste (400 km away) (refs 1 and 2). The peak intensity at 151 and 408 MHz was $\sim 10^{-21}$ W m $^{-2}$ Hz with an upper limit to the dispersion between the two frequencies of ~ 10 s. In the absence of specific data on the γ -ray flux we take a typical value of 10^{-4} erg cm $^{-2}$ corresponding to an energy output of 10^{38} d_{100}^2 erg, where d_{100} is the distance in units of 100 pc.

Here we shall assume that the γ - and radio pulses are physically associated and discuss some implications on the nature of the source. The duration and time lag of the radio pulse are reminiscent of flares in ultraviolet Ceti stars³ where the main activity is in the optical band. However the larger power and temperature required for γ -ray bursts favour models involving white dwarfs or neutron stars.

The brightness temperature of the radio pulse is

$$T_b = (3.2 \times 10^{11})/R^2 d_{100}^2 \text{ K} \quad (1)$$

for a source dimension $R \simeq 10^8$ cm and $d_{100} \simeq 1$, $T_b \simeq 10^{23}$ K — of the same order as found in pulsars. This implies a coherent emission mechanism. Assuming that this is synchrotron radiation, a number of constraints leading to an estimate of the relevant physical parameters can be arrived at. The synchrotron power is⁴ given by the expression

$$\frac{1e^2c^2}{2\pi c \rho^2} \gamma^4 n V N = 4.5 \times 10^{33} \alpha d_{100}^2 \text{ erg s}^{-1} \quad (2)$$

where the observed radio power has been introduced on the right side, α is the beaming factor ($\alpha = 1$ if the emission is isotropic), n is the density of relativistic particles with Lorentz factor γ , ρ is the curvature radius of the particle trajectories, V is the volume of the emitting region and N the coherence factor, which must satisfy the relation

$$N \geq KT_b/\gamma m_e c^2 \quad (3)$$

If the observation frequency is the critical synchrotron frequency one has

$$\nu_{cr} = \gamma^3 \frac{c}{2\pi\rho} = 4 \times 10^8 \text{ Hz} \quad (4)$$

Minimising the energy requirements we further impose that the relativistic particle energy is radiated in the radio band during the crossing time of the emission region R/c

$$\gamma m_e c^2 n V = 4.5 \times 10^{33} R/c \alpha d_{100}^2 \text{ erg} \quad (5)$$

Equations (1), (2), (3), (4) and (5) yield

$$N = 3 \times 10^{15} \gamma^3/R \quad (6)$$

$$N \geq 5.5 \times 10^{31} d_{100}^3/(\gamma R^2) \quad (7)$$

For ordinary synchrotron radiation in a dipole field an addi

tional relation is

$$\rho = \frac{\gamma m_e c}{3 \times 10^6 B_s} \left(\frac{R_s}{R_{s0}} \right)^3 \quad (8)$$

where $\gamma m_e c$ is the electron momentum in eV/c, θ is the pitch angle, and $B_{s0} = 10^{-6} B_s$ (G) is the surface magnetic field and $R_{s0} = 10^{-9} R_s$ (cm) is the radius of the star.

The system gives

$$R_s \geq 1.36 \times 10^3 \theta^{2/7} R_{s0}^{6/7} B_s^{2/7} d_{100}^{2/7} \quad (9a)$$

$$\gamma \geq 20 \theta^{-1/14} B_s^{-1/14} R_{s0}^{-2/14} d_{100}^{6/14} \quad (9b)$$

$$n \leq 10^4 \alpha \theta^{-0.5} B^{-0.5} R_s^{2/14} d_{100}^{10/7} \text{ cm}^{-3} \quad (9c)$$

In the limit where $\theta \rightarrow 0$, the radiation due to particles following the field lines reduces to 'curvature' radiation. For $\rho \simeq R$, one has

$$R_s \geq 4 \times 10^{-3} d_{100}^2 \quad (10a)$$

$$\gamma \geq 140 d_{100}^{2/3} \quad (10b)$$

$$n \leq 10^{10} \alpha d_{100}^{-2/3} \text{ cm}^{-3} \quad (10c)$$

The main difference between the two sets of relations is that in the former case even for a small pitch angle, $\theta \sim 10^{-2}$, a much larger extension is implied. Since it seems extremely difficult to produce and maintain coherence conditions over large scales we suggest that curvature radiation is responsible for the radio-emission. The associated synchrotron radiation is emitted at much higher frequency where presumably it is not amplified by coherence. This picture and the derived values of the parameters are similar to those proposed by Pacini and Rees for pulsars⁶.

Because of the upper limit on the signal dispersion it is not possible to explain the 1-m delay between the γ -ray and radio events as caused by the increasing transparency of an expanding cloud. The delay could be either intrinsic or due to a beaming of the radio emission and to rotation of the source. The period should be a few minutes and the total duration of the radio emission comparable. This could explain the previous negative observations⁶ because one expects that only for a small fraction of the γ -ray events the associated radio emission will be detectable at Earth.

If the underlying star is a neutron star the hypothesis that the delay is intrinsic is difficult to support since the Alfvén velocity is large. The rotational energy of a neutron star with $\omega \simeq 10^{-3}$ and its magnetic energy for $B \simeq 10^{12}$ G are both $\simeq 10^{41}$ erg. In the burst 10^{-3} of the available energy should be released and in both cases this should be accompanied by a pulsar glitch⁷. However the fractional energy variation required is much larger than the maximum observed period discontinuities in pulsars. A possible way out is the interaction with an external agent (for example, a companion star), which on the other hand, implies a serious difficulty in explaining the short timescale⁴.

Production of γ -ray bursts by magnetic white dwarfs has been proposed by some authors⁸⁻¹⁰. The mechanism should be a convective instability, which can account for the similarities with ordinary flares. In this model regions with magnetic fields $\sim 10^8$ - 10^9 G are required⁹, while the average surface field B_s can be lower and, for $B_s \sim 10^6$ G, the burst energy is comparable with the total magnetic energy. On the other hand, from the known density of magnetic white dwarfs in the sun vicinity, a burst frequency of 1/40 per year per star is required in order to account for the observed γ -ray event rate. Therefore either the density of magnetic white dwarfs has been underestimated by a large factor or one must suppose that a

dynamo mechanism can reconstruct the magnetic field at the expenses of the rotational energy, which for $\omega = 10^{-3}$ is 10^{47} erg.

Note added in proof: In a recent preprint by Sommer *et al.* serious doubts are raised on a direct association between the radio and γ -ray events of 16 August 1976.

⁴⁰Ar-³⁹Ar age of rocks, and the development mode of the Philippine Sea

THE origin and development of the Philippine Sea have been central issues in tectonic studies of a marginal sea: the deep-sea drilling project (DSDP), Leg 31, was primarily intended to resolve the question¹. Unfortunately, at only two of the Leg 31 sites (292 and 296) were microfossils indicating the age of the basement recovered, so the age of the ocean basin, had to be deduced by dating the drilled basement rocks. There seems to be some confusion in the literature² in interpreting the fossil data with regard to the age of the ocean basin. We have dated several DSDP Leg 31 drilled rocks by the ⁴⁰Ar-³⁹Ar step-heating technique (Table 1 and Fig. 1) and re-evaluated the fossil ages and various hypotheses concerning the development of the western Philippine Sea and the Shikoku Basin. We applied two statistical criteria to judge the reliability of ⁴⁰Ar-³⁹Ar ages, (1) the experimental data with MSUM values (Table 1) less than 3.50 and (2) the apparent ages should agree with each other, within 1 σ , for more than 65% of ³⁹Ar released. Although such criteria do not prove the reliability of this dating technique, they provide a measure of it³. Of the nine drilling sites, six reached the basement—site 290, 291, 292, 293, 294 and 296—their ages were determined by both the ⁴⁰Ar-³⁹Ar step-heating dating and micropaleontological methods (Table 1).

Earlier views as to the development of the Philippine Sea suggested that the western Philippine Basin is Mesozoic or even older, and the CBF was an extinct oceanic ridge^{4,5}. On the basis of the fossil ages obtained from Leg 31, Karig *et al.*⁶ proposed that the Philippine Basin was a complex early Tertiary basin developed at least in part behind an pre-existing arc system. Loudon⁷ identified ESE-WNW trending magnetic lineations south of the Central Basin Fault as anomalies 18 through 21. Recently, Watts *et al.*⁸ reported ESE-WNW trending lineation north of the CBF, which they suggested as either Mesozoic or Tertiary in age, although preferring the latter. However, there are no Mesozoic basement ages in the western Philippine Sea and no age progression with distance from the CBF, which would be expected if the CBF is an extinct spreading ridge (Fig. 1).

There seems to be considerable difference between the ⁴⁰Ar-³⁹Ar age and microfossil age for site 292. The lowermost clastic rock (chalk: core 39-section 1-88-99) can be identified to belong to P 15 of Blow's planktonic foraminifera zonation scheme⁹ in the late Eocene. If a timescale of Berggren¹⁰, and Berggren and Van Couvering¹¹ is

* $\lambda_e = 0.585 \times 10^{-10} \text{ yr}^{-1}$, $\lambda = 5.305 \times 10^{-10}$, $^{40}\text{K}/^{39}\text{K} = 1.19 \times 10^{-4}$

†Total age = $(1/\lambda) \ln \{1 + J(^{40}\text{Ar}-^{39}\text{Ar})_{\text{total}}\}$, where $(^{40}\text{Ar}-^{39}\text{Ar})_{\text{total}} = \sum f_i(^{40}\text{Ar}-^{39}\text{Ar})_i$, f_i = fraction of ³⁹Ar released.

‡Defined for the fraction of ³⁹Ar released, which is indicated in a bracket.

§Determined for the experimental data (temperature fractions) by means of York's least square fitting method.

||The isochron and plateau ages were determined only for three lowest temperature fractions; 600, 700, 800 °C. Hence, the age may not be very reliable.

adopted, the age would be approximately 41 Myr BP. An ⁴⁰Ar-³⁹Ar age obtained for a basalt (about 16 m below the chalk sample) gives 47.5 Myr BP (Fig. 1) although this age difference may be due to a depositional hiatus. A K-Ar age obtained by McKee¹² for Core 45 (38.1 Myr BP) and Core 47 (37.1 Myr BP) may reflect Ar-loss or some alteration effects, since the K-Ar ages are even younger than the microfossil ages in the overlying sediments (Core 41) which is about 40 cm above the basalts. Although nannofossils,

were tentatively assigned the lower Pliocene age for the basalt part of the Hole 293, their rarity means that the data are highly questionable. As the basalt sample used for ⁴⁰Ar-³⁹Ar dating is brecciated gabbro¹, the radiometric age is unlikely to represent the basement age. Hole 294 is the northernmost drilling site in Philippine Sea and also furthest from the CBF. If the CBF was truly a spreading ridge axis, one would expect to find the oldest age at this site, but this is not the case.

Fig 1 a, DSDP Leg 31 sampling sites; ⁴⁰Ar-³⁹Ar ages (Myr) and minimum basement ages estimated by microfossils are shown in a bracket (left). b, the fossil dates and ⁴⁰Ar-³⁹Ar ages are plotted against a depth below the sea bottom for site 292 and 296, which are only sites in Leg 31 to show a reliable basement fossil age.

Summarising, the western Philippine Basin is very likely to be Tertiary in age, there is no positive age evidence to suggest the spreading ocean ridge origin of CBF and the Philippine Basin is significantly younger than the currently proposed magnetic anomaly lineations would imply⁴⁻⁷.

Several authors¹²⁻¹⁵ have identified magnetic anomaly lineations in Shikoku Basin suggesting a spreading origin for the Basin. Using Leg 31 data, Watts and Weissel¹⁶ estimated the oldest age of the basement to be 24 to 27 Myr BP, and that the east-west-directed spreading of Shikoku Basin started about the same time. Only one ⁴⁰Ar-³⁹Ar age has been obtained for lapilli tuff at site 296, located on the Kyushu-Palau Ridge, and this is considerably older than the assumed basement age¹⁶. Site 296 shows gradational change from purely lapilli tuff to pure clastic rock (mainly nannofossil chalk); in Core 38, *Eulepidina*, a larger foraminiferan, indicated shallow water habitat around the middle (Core 56 and 57) of this changing interval¹. These results suggest that the pyroclastics accumulated in a rather shallow sea which then subsided. An average sedimentation rate of about 2.72 cm per 1,000 yr can be estimated for the time interval from 22.5 Myr BP (M/O boundary detected by planktonic foraminifera) to 47.5 Myr BP (⁴⁰Ar-³⁹Ar age) (Fig. 1) which is significantly faster than that of the overlying sediments. The ⁴⁰Ar-³⁹Ar age result is, therefore, in accordance with that expected from the sedimentation rate. The difference between the ⁴⁰Ar-³⁹Ar age and the assumed basement age indicates that either the opening of the Shikoku Basin was a much later event than the formation of the Kyushu-Palau Ridge, or, that the identification of the magnetic anomaly lineation is in error. To resolve the question more radiometric ages of the basement rocks in Shikoku Basin are needed.

The ⁴⁰Ar-³⁹Ar age of the lapilli tuff, seems to favour a suggestion¹²⁻¹⁶ that Shikoku Basin, as well as Parece Vella Basin, was formed by rifting of the Izu-Bonin-Mariana Islands Arc. If the Shikoku Basin was formed this way DSDP site 296, now on the Kyushu-Palau Ridge, was once located on the Izu-Bonin-Mariana Island Arc, or else there should be some similarity between the basement rocks of the Kyushu-Palau Ridge represented by Site 296 materials and of the Izu-Bonin-Mariana Island Arc. In the latter augite-orthopyroxene andesite from Hahajima of the Bonin islands gave a K-Ar age of 40.1 ± 1.2 Myr BP (ref. 17) and dacite from Saipan of the Mariana Islands yielded an age of 45 Myr BP. Both the ages are consistent with larger foraminifera evidence from these islands and similar to that for site 296 (ref. 18). In addition Meijer¹⁹ found Pb isotopic ratios in andesite from the Site 296 which were quite similar to those found in volcanic rocks from Iwo-Jima, south of the Bonin Islands, both were very different from typical oceanic basalt Pb isotopic compositions, but were similar to those from the island arcs. These facts, therefore, indicate genetic similarities between site 296 basement materials and the Izu-Bonin-Mariana island arc, favouring the rifting apart theory of the origin of the Shikoku Basin.

Alpha-induced coloration reversal in biotite

Using previously developed techniques for the investigation of radiation coloration in biotite, we have discovered the hitherto unknown fact that the onset of reversal occurs precisely at the end of the α range and is a phenomenon independent of the darkening peak.

Since the earliest original investigations of Joly¹ into the nature of pleochroic haloes, it has been known that α radiation can produce a 'reversal' effect in biotite (sometimes called 'inversion'). The usual effect of natural or artificial α irradiation is to produce a characteristic darkening of the biotite. This darkening increases with dose until a certain point (that is, the optical absorption coefficient saturates) and then the mineral begins to lighten as the dose is further increased. With sufficient dosage it is possible to lighten the biotite to the point where it actually becomes less dark than its naturally occurring shade.

The most quantitative study of reversal was carried out by Deutsch^{2,3} and his collaborators. Their technique involved the irradiation of small flakes of biotite with non-collimated radon α particles. They found that in their experimental configuration reversal took place at doses over approximately 10^{17} alphas cm^{-2} which is about four orders of magnitude beyond the onset of darkening. They also determined that the decrease in darkening near saturation. Other important halo investigators before and after Deutsch have also remarked on the reversal phenomenon^{4,5}.

Using techniques of Van de Graaff irradiation of biotite and precision photomicrography which have been described elsewhere⁶, we have discovered a hitherto unknown feature of reversal. In the literature it is implicit that reversal occurs at the point of maximum darkening or, at least, is related to the ionisation which causes the darkening peak. We have found that in fact reversal does not begin at the darkening peak, but at the foot of the peak at a point corresponding to the α -extrapolated ionisation range in biotite which is $35.1 \mu\text{m}$ at 7.69 MeV (ref. 6).

The most significant conclusion from these results is that the reversal process is associated with the depositing of α -particles at the end of their range and is not an effect due to ionisation, as is the darkening. In other words, the physical mechanisms of darkening and reversal seem to be quite different.

Figure 1 shows the optical absorption coefficient for four successive α -irradiations of the same piece of biotite. (As in ref. 6 we used a specimen from the Faraday pegmatite in Bancroft, Ontario, Canada.) For clarity we used the maximum ²³⁸U α -family energy, 7.69 MeV. The successive development of the reversal is readily apparent. The minimum of reversal corresponds within the error of measurement to the extrapolated ionisation range as given above. Our work, based on the results shown in Fig. 1 and other bombardments, indicates a reversal onset at approximately 5.2×10^{14} alphas cm^{-2} . We have found a plateau area of at

Fig. 1 These curves are densitometer tracings, suitably processed according to the method of ref. 6, of single-energy α bombardments of biotite. For each curve the ordinate is the optical absorption coefficient (in units of the natural coefficient for the biotite so that $\mu = 1$ is the unirradiated mineral). All four energies were 7.69 MeV and the doses, from top to bottom were approximately 2.6×10^{14} alphas cm^{-2} , 10^{15} alphas cm^{-2} , 2.1×10^{15} alphas cm^{-2} , and 4.0×10^{15} alphas cm^{-2} . Note the distinct separation between the maximum coloration at $32.2 \pm 0.2 \mu\text{m}$, and the reversal at the extrapolated ionisation range of $35.1 \pm 0.2 \mu\text{m}$.

most one order of magnitude between saturation and the onset of reversal. Our onset of reversal dose is several orders of magnitude below that found by Deutsch and our plateau area somewhat smaller. We do not consider that these conflict with Deutsch's results considering the precision of our work and his semi-quantitative approach. We repeat, however, that the reversal onset does not occur at the same place along the α track as does the darkening peak. The latter occurs at the point of maximum ionisation⁶.

Previous explanations of reversal go back to Joly who believed the halo development process to be a photographic-like one with a latent image being 'developed' by the α radiation. He attributed the reversal to some unspecified 'photographic' effect. Henderson and Turnbull⁴ made Joly's conjectures more specific by attributing the reversal to an Eberhard-like effect in the biotite. In the development of a negative the Eberhard effect causes regions adjacent to sharply defined dense areas to become lighter than they should due to a diffusion into the affected regions of an excess of soluble bromide. This misinterpretation of the Eberhard effect caused Henderson and Turnbull to underestimate the alpha ranges when determined from reversal haloes⁴. As our Fig. 1 shows, the reversal effect has a distinct and sharply defined onset and is not at all characteristic of an effect diffusing from the darkening peak outward.

Deutsch and Janssens also considered the geological phenomenon of metamictisation and concluded after some simple calculations that this could not be the cause of reversal.

The phenomenon of reversal does not seem well known in solid state physics. It would be of interest to α -bombard some well understood system, such as an alkali halide, to see if colour reversal could be obtained.

We thank R. Ward for providing us with biotite specimens and A. Barrett who provided access to and assisted with the densitometer. We also thank A. M. de Graaf for helpful discussions.

The Thera eruption and Late Minoan-IB destructions on Crete

MARINATOS' theory¹ of the decline of the Minoan civilisation by paroxysmal volcanic events of the Thera volcano is widely accepted, and many papers on the topic have been published, especially since the International Scientific Congress on the Volcano of Thera². The main and controversial problem is the fact that the simultaneous devastations of numerous Late Minoan (LM) IB sites and palaces in Crete are dated archaeologically (concerning the development of Minoan pottery) as 30-50 yr later than the destruction of the important LM settlement on Santorini (Acrotiri ruins)³. Following Marinatos' theory, that the devastations in Crete were caused by the Thera volcano, two eruptions (if

chronology is correct) must have occurred. The first, destroying the LM-IA settlements on Santorini, in about 1500 BC, the second, causing the LM-IB destructions in Crete, about 1450 BC. According to a recent theory, only LM-IA destructions on Crete are connected with the Thera outburst^{4,5}. We report here fieldwork on Santorini which shows clearly that neither products of two volcanic outbursts nor of a 'two-phase' eruption⁶, differing in a time interval of about 50 yr, exist, and that the collapse of the Santorini caldera, which caused devastating earthquakes and tsunamis in Crete, did not occur about 50 yr after the volcanic paroxysm.

If two eruptions had occurred, volcanic products of both would exist. In that case, the time interval between both volcanic events should be manifested by an erosional disconformity and a weathered layer dividing the products of the two eruptions. From the volcanological point of view, the experts are unanimous that the Upper Pumice Series⁷, which covers the destroyed LM settlements on Santorini, was deposited during a single volcanic phase. We carried out new fieldwork on Santorini in autumn 1976 which confirmed this current view. According to the stratigraphy and lithologic character of the Upper Pumice Series⁸ the LM outburst began with catastrophic earthquakes that, after an interval between some weeks and 2 yr (ref. 2), were followed by a large pumice-fall. This pumice-fall layer is overlain by base surge deposits⁹, which locally show a slight erosional break. It should be stressed, however, that this break represents only a very short span of time of volcanic inactivity, that is of some days up to at most few weeks. The eruption culminated in some violent ash-flow eruptions by which the bulk of the Upper Pumice Series was deposited. These eruptions were connected with the beginning of the collapse of the central part of the old

Santorini island. This is evidenced by abundant huge lithic blocks, as much as 3 m in diameter, embedded in the ash-flow material. These blocks were formed by a falling-in of parts of the old volcanic pile along circular and/or polygonal fractures. Still in the course of the collapse the blocks were ejected immediately by simultaneous paroxysmal eruptions. This evidence is inconsistent with Doumas' theory¹⁰ of a formation of the Santorini caldera about 50 yr after the Thera outburst, that is around 1450 BC. This theory should explain the time interval between the devastations both on Santorini and in Crete.

According to our investigations on Santorini and Crete, the devastations in Crete around 1450 BC can be explained only by the following alternative. (1) The archaeological dates must be revised. The destructions on Santorini and in Crete occurred simultaneously (both around 1500 BC or both around 1450 BC).

From the archaeological point of view, a modification of the ceramic chronology is not supported and would, moreover, involve insuperable difficulties. (2) The devastations in Crete were caused neither by the eruptions of the Thera volcano nor as a result of the subsidence of the Santorini caldera.

The results of our fieldwork are inconsistent with the theory that the LM-IB devastations in Crete were the consequence of a volcanic disaster on Thera. According to this theory^{1,11,12,13,14} the LM-IB devastations on Crete have been caused by tephra-fall and/or tsunamis and/or catastrophic earthquakes, connected with the Thera outburst or the Santorini caldera collapse.

Tephra-fall: Our fieldwork showed that visible remnants of the LM tephra-layer in central and eastern Crete do not exist. Special attention was paid to localities in which such remnants should have been preserved, for example in

Fig. 1 The most important Late Minoan sites on Crete and the location of Thira (Santorini) and other Cycladian islands.

Fig. 2 Isoseismic sketch map of Crete of the great regional earthquake from June, 26, 1926. The relation of the earthquake intensity to the block structure of Crete is clearly visible. (According to Sieberg²¹.)

recent soil profiles at the northern coast, exposed by deep open cuts and drain channels or in crevices and sinks in the limestone mountains around the Lasithi plateau. Residues of some washed soil samples (from Pargos and Malia) contain few small grains of volcanic origin, that is, feldspar, volcanic glass ($n \sim 1.510$, which corresponds to the Upper Pumice Series on Thera⁸), and rare pyroxene. Their meagre quantity, however, is inconsistent with a suggested thickness of the tephra-layer of up to 10 cm (ref. 6) or even of 1 cm (ref. 15). Quantities of 50–750 volcanic particles per cm^3 as indicated by Boekschoten¹⁴, have never been found. The discrepancy between the refractive index of the glass shards in Boekschoten's samples, that is, $n \sim 1.503$, and the index of the volcanic glass of the Upper Pumice Series ($n \sim 1.510$, ref. 8), was already stated¹⁴. In other publications dealing with the presence of LM volcanic tephra on Crete^{16,17} is reported that only traces of such tephra have been found, the highest concentrations only in Minoan settlements.

There is a simple explanation for such a presence of pumice particles in these settlements, namely the use of pumice in workshops and in households. Lumps of pumice were already used by Minoan people for various purposes. This is illustrated by findings of numerous lumps and blocks of pumice (up to 30 cm in diameter) in Malia, Gournia, Knossos and Kato Zakros. Because of its size this pumice could not have reached Crete by way of an even paroxysmal volcanic eruption on Santorini, Milos or Nisyros. This material was mainly imported from these islands. Pieces from Malia, Knossos and Kato Zakros are characterised by grooves and traces of working.

The volcanic ash horizons in eastern Mediterranean cores, which were attributed to the Thera outburst and considered as an evidence of an important ash-fall in Crete and the surrounding Aegean Sea¹¹, are of three or four different ages¹⁸. The abnormal local thickness (as much as 212 cm) (ref. 11) of ash-layers in some cores is due to post-depositional mixing and transport. Furthermore, new problems concerning the stratigraphic correlation of these ash beds in the eastern Mediterranean cores have been pointed out¹⁹. The distribution chart of the tephra from the LM

Thera outburst, "imaginative but very uncritically"¹⁸ constructed by Ninkovich and Heezen¹¹, must therefore be discarded as one of the chief arguments for a disastrous tephra-fall on Crete.

Tsunamis: According to our observations in Amnisos, Megaron Nirou, Malia, Gournia and Kato Zakros the force of tsunamis originated by volcanic or seismic events in connection with the Thera outburst must have been more shallow than previously supposed¹⁴. According to our calculations, the uppermost height of the tsunamis amounts to only 8–10 m (ref. 20).

Volcanic earthquakes: The devastations in Crete about 1450 BC could not have been caused by volcanic earthquakes because the Thera outburst occurred about 50 yr earlier.

We conclude from the above that all non-human devastations around 1450 BC in Crete, that is, that of Amnisos, Megaron Nirou, Malia, Gournia, Kato Zakros on the northern and eastern coast and that of Pargos, Phaistos and Hagia Triada on or near the southern coast of Crete (Fig. 1)²⁰, have been caused by a catastrophic regional earthquake, similar to that of AD 1926 (refs 14, 21). The complicated block structure of Crete (Fig. 2) is the reason that, as during the great recent earthquakes (1926, 1856, 1846, 1815, 1780 and so on)²¹, tectonically unstable regions have violently been affected. More stable regions were only slightly touched. This regionally different behaviour of Crete with respect to earthquakes is consistent with the fact that the palace of Knossos was not demolished during the regional earthquake around 1450 BC. The same phenomenon was observed in 1926, when Evan's reconstructions of Knossos did not suffer but the neighbouring Iraklion was strongly demolished.

According to our observations there is no connection between the decline of the Minoan civilisation and the Thera outburst. This volcanic paroxysm occurred around 1500 BC and did not have a revival around 1450 BC, at a time of the great devastations in Crete. All speculations that the Thera outburst should have caused 'a large natural catastrophe in three stages', that is the plagues of Egypt, the deluge of Deukalion and the submergence of Atlantis¹⁴

are imaginative but, from the scientific point of view, not convincing.

Charge stabilisation of very small particles of mixed oxides

IN our laboratory, a rock salt type structure has been found for mixed oxides of the type $Me(II)_xCr(III)_{2/3(1-x)}O$. $Me(II)$ can be Co, Ni, Cu, and Zn or mixtures of these. Other authors^{1,2} have found similar compounds of the general formula $Me(II)_xMe(III)_{2/3(1-x)}O$. We suggest a structure where a very small particle, of the order of 2–10 nm, has been stabilised by a surplus of O^{2-} ions on the surface, compensating an excess positive charge uniformly distributed in the bulk.

Besides the presence of $Me(II)_xCr(III)_{2/3(1-x)}O$, X-ray analysis shows MeO in varying small amounts. The particle size, as determined by X-ray diffraction, is typically in the order of 3–10 nm. In addition, there is a size dependence of the lattice parameter such that a small particle will have a relatively smaller lattice parameter of 412 pm, whereas for a 10 nm particle it will be around 420 pm.

From the structural data, one may conclude that the cations are randomly distributed on the octahedral sites in the crystal. Any ordered arrangements of these, or occupation of other sites, would destroy the rock salt structure. From electron diffraction and microscopy, it seems that in particular the (111) face is towards the vacuum side. In the zinc case, epitaxial ZnO (001) on $Zn_xCr_{2/3(1-x)}O$ has been observed (Fig. 1). Below 400 °C, the structure is stable in wet and dry atmospheres. Above this temperature, spinel phase and/or MeO/Cr_2O_3 is formed in an irreversible process.

As a possible explanation of these observations, we suggest a model where the particle surface has become negatively charged. If we, for simplicity, consider a finite linear chain of Me^{2+} , O^{2-} ions, the energy per O^{2-} ion would be lower than in the corresponding infinite chain. Substitution of 2 Cr^{3+} for 3 Me^{2+} and rearrangement of the chain so that both endpoints are occupied by O^{2-} ions results in a more stable configuration where the energy per O^{2-} ion is higher than in the infinite. The energy depends inversely on the chain length. For a bulk crystal with rock salt structure we may perform a similar process. Let us consider a small cube of NiO with an edge

Fig. 1 Transmission electron diffraction patterns of a mixture of ZnO and $Zn_xCr_{2/3(1-x)}O$. The intense 6-fold symmetry spots arise from the (001) plane in ZnO while the less intense 6-fold symmetry spots are due to the (111) planes of the mixed oxide phase.

length of $\sim na$, where a is the lattice parameter ($= 418$ pm). The cube contains $4n^3$ NiO pairs; $12n^2$ of the sears located on the surface, edges and corners of the cube. Substitution of 2 Cr^{3+} in this lattice for 3 Ni^{2+} creates one cation vacancy. The surface acts as a sink for the vacancy and eventually 1 Ni^{2+} will be removed from the surface resulting in a negative charge of $-2e$ on the surface. It should be added that the Madelung energy of the Ni^{2+} is higher in the bulk than on the surface, making this process favourable. Assuming that the process is favourable as long as there are cations left on the surface, we end up with a crystal with

$$\begin{aligned} 4n^3 O^{2-} \\ 24n^2 Cr^{3+} \\ 4n^3 - 32n^2 Ni^{2+} \end{aligned}$$

$$so \quad x = 1 - \frac{9}{n}$$

For the size mentioned (~ 5 nm), n is about 12 corresponding to $x \approx 0.25$. Thus for small n the Cr^{3+} concentration becomes appreciable. On the other hand, this will result in a smaller lattice parameter, since the ion radius of Cr^{3+} is less than the ion radius of Me^{2+} . Two other energy contributions may stabilise this arrangement. Firstly, the smaller lattice parameter will result in a larger Madelung energy. Secondly, the Cr^{3+} ion has a sizeable octahedral configuration energy.

In the case of an octahedron, the surface-to-bulk ratio is higher than for the cube. Besides, we may construct the crystal so that it has the negatively charged (111) planes towards the vacuum side. Electron diffraction indicates that this is a likely arrangement (Fig. 1).

In order to estimate the energy changes in such an arrangement one should calculate, in addition to the Madelung energy, the attractive energy from the bulk surface interaction, as well as the repulsive energies from the negatively charged surface and from the positively charged bulk. This is not easily done, for a cube or for an octahedron. An estimate of the relative magnitudes involved, however, can be obtained by considering a 'spherical crystal' where the excess positive charge in the bulk is compensated for by a corresponding negative charge on the surface. We are not, in this argument, considering the repulsive potential between nearest neighbour ions, since this should be relatively independent of the various configurations we are considering.

Let N be the number of O^{2-} ions. The maximum number of O^{2-} in the surface is then given by $kN^{2/3}$.

We then have $2kN^{2/3}Cr^{3+}$ ions and $N-3kN^{2/3}Ni^{2+}$ ions. The surface has a total negative charge of $-2kN^{2/3}e = -Q$. Similarly, the bulk has an excess positive charge of $+Q$.

Using the superposition principle, one may calculate the electrostatic energies involved. Firstly, there is a Madelung energy from the lattice, being approximately

$$U_M = -\frac{\alpha}{a} \frac{1}{4\pi\epsilon_0} 4e^2 \left\{ \left(N - 3kN^{2/3} \right) + \frac{3}{2} 2kN^{2/3} \right\} \\ = -\frac{4\alpha}{a} \frac{e^2}{4\pi\epsilon_0} N \quad (1)$$

where $\alpha \approx 3.50$ is the Madelung constant and the first term represents MeO , the second (approximately) Cr_2O_3 .

Furthermore, there are the Coulomb energies from this particular charge arrangement.

$$U_C \approx \frac{Q^2}{4\pi\epsilon_0 r} \left(\frac{1}{2} + \frac{3}{5\epsilon} - \frac{1}{\epsilon} \right) = \frac{Q}{4\pi\epsilon_0 r} \left(\frac{1}{2} - \frac{2}{5\epsilon} \right) \quad (2)$$

the three terms in the bracket representing the surface repulsive energy, the bulk repulsive energy, and the attractive energy from the surface bulk interaction; ϵ is the dielectric constant. Inserting the value of Q and using $r = k_1 N^{1/3} a$, we find

$$U_C = \frac{k^2 N^{4/3} e^2}{4\pi\epsilon_0 r} \left(\frac{1}{2} - \frac{2}{5\epsilon} \right) \approx \frac{2.6 k^2 N}{4\pi\epsilon_0 a} e^2 \left(\frac{1}{2} - \frac{2}{5\epsilon} \right) \quad (3)$$

The maximum value of k is of the order three, whereas values of ϵ for very small particles are not known, but are most likely to be greater than one. The Coulomb term as such is then positive. In the limit for small spheres $\epsilon \rightarrow 1$ and

$$U_C \approx \frac{k^2}{4} \frac{Ne^2}{4\pi\epsilon_0 a} \quad (4)$$

The stability requirement is that the pair energy should be lower than for a pair in a cube of a similar size. For pure MeO , this is the stable configuration. The most stable configuration is obtained by minimising the expression for the total energy per O^{2-} ion with respect to N and k . Madelung energies of small cubes have been calculated by Christov³. Here we will use the approximative expression

$$U_0 \approx -\frac{4\alpha}{a_0} \frac{e^2}{4\pi\epsilon_0} \left\{ N - 0.24 N^{2/3} \right\} \quad (5)$$

where a_0 is the lattice parameter of pure MeO , and the last term in the bracket represents the smaller energy of surface and edge pairs.

A strongly charged surface will bind polar molecules such as water very strongly. A bonding energy of 200 kJ mol^{-1} will contribute about $-0.75kN^{2/3}e^2/4\pi\epsilon_0 a$

Including this, we obtain for the energy in the case of $k = 2$

$$U \approx \frac{-e^2}{4\pi\epsilon_0 a} N(14 - 1.0 + 1.5 N^{-1/3}) \quad (6)$$

The stability region is determined by $U/U_0 \geq 1$.

$$\text{Thus} \quad \frac{a_0}{a} \frac{13.0 + 1.5N^{-1/3}}{14 - 3.4N^{-1/3}} \geq 1 \quad (7)$$

The ratio a_0/a is a function of N . It represents the gain in Madelung energy by contraction of the lattice. Using Vegard's law and suitable values for ion radii we obtain in the present approximation $N \leq 1000$.

For $k = 1$, we obtain $N \leq 30,000$. If, instead, we used the pair energy of the infinite crystal as a stability limit, we would obtain $N \leq 600$ for $k = 1$. Thus, the model qualitatively explains the relative stability of small particles of mixed oxides. A similar situation could exist for other systems. It might also explain the growth of octahedral crystals of $NaCl$ and KCl under various circumstances.

I thank Jørgen Villadsen, who introduced me to the structure and properties of the mixed oxides, and to Haldor Topsøe A/S for permission to publish this work.

State of iron in glass-like carbon prepared by heat treatment of ferrocene resin

We have investigated the conversion of organometallic polymers to inorganic materials by heat-treatment. Several of those inorganic materials are industrially useful. Earlier studies have been reported in this journal^{1–3}. We describe here the state of iron dispersed in a glass-like carbon, which was prepared by heat-treatment of an organometallic resin containing ferrocene skeletons as the main chain. This state is unusual and strange both physically and chemically.

The organometallic resin was synthesised by the polycondensation of acetylferrocene and furfural using sulphuric acid as the catalyst⁴. When the molar ratio of furfural (F) and acetylferrocene (A) exceeded $F/A = 15$, the resin was not formed. Acetone was added to the starting material which contained furfural at an F/A ratio above 15 (ref. 7). The resins obtained were named 2-resin, 5-resin, 10-resin, 20-resin, 30-resin, 40-resin and 100-resin. The number indicates the number of moles of furfural for 1 mole of acetylferrocene in the starting material. To examine the physical and chemical state of the iron by Mössbauer spectroscopy, 30- and 100-resins were prepared using ferrocene consisting of ⁵⁷Fe enriched to 62.5% (ref. 8). The resin was heated in a vacuum of $1 \times 10^{-3} \text{ mmHg}$ from room temperature up to 350°C for 4 h, then up to 400°C for 2 h. The heat-treated resin, still in its evacuated container, was

Table 1 Elemental analyses of resins heat-treated at 400 °C

Sample	Fe (wt%)	C (wt%)	H (wt%)	O (wt%)*
2-resin	13.20	69.07	3.68	14.05
5-resin	10.60	71.08	3.22	15.10
10-resin	7.96	72.01	3.58	16.45
20-resin	3.65	73.33	3.65	19.37
30-resin	2.54	75.06	3.77	18.65
40-resin	2.06	76.36	3.69	17.89
100-resin	1.00	77.14	3.78	18.08

* The percentage of oxygen is obtained by subtracting the percentages due to iron, carbon and hydrogen from 100.

placed in a glove box filled with argon; this was used for each measurement.

The resins heat-treated at 400 °C were susceptible to oxidation. In particular, 10-resin was pyrophoric on exposure to air. In the resin heat-treated at 400 °C, therefore, the iron liberated from the ferrocene skeleton would be present as ultra-fine particles or in a low valence state (i.e. Fe^+ or Fe^{2+}). As ferrocene is decomposed by heat-treatment above 400 °C, iron carbide is not formed but metallic iron is produced⁹. So there is probably no iron carbide in the resins heat-treated at 400 °C.

Fig. 1 Electron micrographs of the resins heat-treated at 400 °C, *a*, 2-resin; *b*, 100-resin.**Fig. 2** Mössbauer spectra of the resins heat-treated at 400 °C (4.2 K); *a*, 2-resin; *b*, 10-resin; *c*, 30-resin; *d*, 100-resin.

Infrared spectra showed that the resin structure was decomposed by heat-treatment at 400 °C (ref. 7). The X-ray diffraction patterns indicated that the matrix of heat-treated resin was a glass-like carbon. Results of elemental analysis of the heat-treated resin are shown in Table 1. Electron micrographs of 2- and 100-resins heat-treated at 400 °C are shown in Fig. 1. As shown in Fig. 1*a*, in 2-resin iron particles 10–25 Å in diameter were dispersed uniformly in the glass-like carbon, and larger iron particles (30–150 Å) were thinly scattered. This dispersion was also observed in 5- and 10-resins heat-treated at 400 °C. In 20- and 30-resins heat-treated at 400 °C, iron particles of irregular size (10–150 Å) were dispersed in the glass-like carbon matrix. However, in 40- and 100-resins heat-treated at 400 °C no iron particles were visible, as shown in Fig. 1*b*; the iron particles were evidently below 10 Å in size. In Table 2 are shown the X-ray diffraction data of 2-resin heat-treated at 400 °C (Table 2). The ultra-fine particles included iron of hexagonal close-packed (h.c.p.) ($a_0 = 3.30$, $c_0 = 5.21$) and distorted body-centred cubic (b.c.c.) ($a_0 = 2.95$) type structures. Iron of h.c.p. type structure has previously only been recognised at high pressures of 130 kbar and above¹⁰. These iron particles of h.c.p. and distorted b.c.c. type structures corresponded to those of 10–25 Å in Fig. 1*a*. Diffraction peaks due to the iron particles of 30–150 Å were not observable, since they were small in number. The X-ray diffraction patterns of 5- and 10-resins heat-treated at 400 °C were similar to that of 2-resin. No diffraction peaks due to iron particles were detectable in the other resins heat-treated at 400 °C. Mössbauer spectra of 2-, 10-, 30-, and 100-resins heat-treated at 400 °C are shown in Fig. 2. In the Mössbauer spectrum of 2-resin, four peaks marked M were due to magnetic splitting of ferromagnetic iron. The isomer shift of the two peaks marked Q was $+0.21 \pm 0.03 \text{ mm s}^{-1}$;

Table 2 X-ray diffraction data of ultra-fine iron particles in 2-resin heat treated at 400 °C.

Hexagonal close-packed iron		Distorted body-centred cubic iron	
$d(\text{Å})$	(hkl)	$d(\text{Å})$	(hkl)
2.85	(100)	2.09	(110)
2.61	(002)	1.48	(200)
2.51	(101)		
1.61	(110)		
1.48	(103)		
1.39	(112)		
1.30	(004)		
1.10	(203)		

the separation was $1.44 \pm 0.03 \text{ mm s}^{-1}$. These peaks were possibly due to the quadrupole splitting of h.c.p. iron. The peak marked I at $+1.70 \pm 0.03 \text{ mm s}^{-1}$ was attributed to Fe^+ , because the large isomer shift value agreed with that published for Fe^+ (ref. 11). The peak marked C, at $-0.08 \pm 0.05 \text{ mm s}^{-1}$, was due to iron cluster, because the isomer shift corresponded to that of iron cluster¹². In 10-resin, the peaks due to the magnetic splitting were weaker. In 30-resin, the peaks due to the quadrupole splitting were weaker, and the magnetic splittings were not detected. In 100-resin, only slight quadrupole splittings remained. That is to say, as the iron content in the resin decreases, the peaks due to the magnetic splitting and the quadrupole splitting successively weaken and disappear. The peaks due to iron cluster and Fe^+ are present. In the inorganic glass-like carbon prepared by heat-treatment of the acetyl-ferrocene-furfural resin, the liberated iron is in ultra-fine particles as shown in Fig. 1. The size of iron particles increases probably in the order of cluster, h.c.p. iron, distorted b.c.c. iron, and b.c.c. iron. In the resin heat-treated at 400°C , Fe^+ ion is stabilised. In the present study, however, it could not be shown how the Fe^+ ion is bonded chemically to the glass-like carbon matrix.

Bomb ^{14}C and human radiation burden

RADIOACTIVE fallout from nuclear weapon tests has resulted in a significant increase in mean radiation dose received by the world's population. While fission nuclides such as ^{137}Cs and ^{90}Sr are important sources of internal radioactivity, notable characteristics of artificial ^{14}C production are (1) its long half-life ($5,730 \pm 40 \text{ yr}$), (2) easy access via the food chain to all key molecules of body tissue, and (3) relatively long residence times in both stratosphere and troposphere of four and eight years respectively² (cf. mean residence time of particulate nuclear debris in the troposphere $\sim 30 \text{ d}$ ^{3a}). Although ^{14}C emits a low-energy β -particle ($E_{\text{max}} = 156 \text{ keV}$), its ease of incorporation in genetic material and the associated implications have provoked concern among several eminent scientists over artificial production of this radionuclide, even prior to the major testing period⁴⁻⁷. Recent data on levels of bomb ^{14}C and residence times of carbon in the human body are now available⁸. Thus excess human radiation burdens from this radioisotope are evaluated in this article under the assumption that no radiation dose, however small, can be regarded as entirely harmless biologically. This assumption, albeit a major one, is still adopted for radiation hazard considerations in the absence of conclusive evidence otherwise.

The absorbed dose, D_N , to soft tissue/bone marrow and bone-lining cells from decay of natural ^{14}C is $0.69 \text{ mrad yr}^{-1}$ and $0.74 \text{ mrad yr}^{-1}$ respectively. Since ^{14}C concentrations during the nuclear era are normally quoted as percentage

excess, $\Delta(\%)$, over the natural level, corresponding ^{14}C doses are directly expressed as $D_N(1 + \Delta/100)$. Annual absorbed doses from ^{14}C , both natural and man-made, are estimated for 1953–1973 (see Fig. 1) using $\tau = 6 \text{ yr}$ and $\tau = 30 \text{ yr}$ as representative mean values of residence times of carbon in soft tissue and bone collagen respectively⁸. Plotted values apply to mature tissue but may be used with minimal error for tissues under growth, with the exception of bone collagen. For this latter component, an approximate dose is estimated using conditions of linear increase in collagen with no carbon turnover. In this situation, the annual dose for a 20-yr old is simply the averaged annual dose contributions received before this age and reaches a maximum of $1.07 \text{ mrad yr}^{-1}$ for bone-lining cells, delivered in 1984 to individuals born in 1965.

Fig. 1 Annual absorbed doses attributable to ^{14}C , 1953–1973. Total doses (natural + bomb ^{14}C) were calculated using tissue ^{14}C curves of Fig. 3, p.830; $\tau = 6 \text{ yr}$ and $\tau = 30 \text{ yr}$ were assigned as residence times to soft tissue/bone marrow and bone-lining cell carbon respectively. Natural ^{14}C dose rates were determined via theoretical consideration of the Suess effect¹⁰. ---, bone-lining cells; —, soft tissue/bone marrow.

Annual radiation doses for years 1975–2025 (see Fig. 2) are based on corresponding tissue ^{14}C levels. The latter data depend on future dietary ^{14}C content which has been estimated using (1) observed mathematical functions of atmospheric and oceanic ^{14}C levels⁹, and (2) a similar ocean water function but with an atmospheric ^{14}C activity decrease of 2% per yr, the present rate of decrease. The major uncertainty in Fig. 2 is associated with prediction of future atmospheric ^{14}C levels. With no further appreciable artificial production of this radioisotope, however, atmospheric ^{14}C content should reach pre-bomb levels by 2025, essentially via exchange of carbon with the oceans, and by dilution with inactive CO_2 (Suess effect). Again, natural ^{14}C data are included in Fig. 2, with estimates based on theoretical predictions of atmospheric $^{14}\text{CO}_2$ activities under the influence of the Suess effect alone¹⁰. Thus although environmental ^{14}C levels will approach pre-bomb concentrations by the first half of next century, net contributions from artificially produced ^{14}C are still appreciable.

For pertinent evaluation of possible biological effects of this radiation, total radiation received by any tissue over its critical years of function is more relevant than individual annual doses. Examples of cumulated doses to gonads (over 30 yr) and to bone marrow and bone-lining cells (over 60 yr)

Fig. 2 Predicted annual absorbed doses attributable to ^{14}C , 1975–2025. Total doses to soft tissue/bone marrow and bone-lining cells were calculated from predicted tissue ^{14}C levels which are closely related to environmental ^{14}C activities. The latter data in line (a) were based on predicted future atmospheric and oceanic ^{14}C contents⁹, and in line (b) were based on an atmospheric decrease in ^{14}C content of 2% yr^{-1} . Natural ^{14}C dose rates were assessed as in Fig. 1. Linear extrapolation of upper curves (a) indicates that the total absorbed doses to soft tissue/bone marrow and bone-lining cells will return to natural levels by years 2035 and 2050 respectively. —, Bone-lining cells; —, soft tissue/bone marrow.

have been determined (see Table 1). Evaluation of the long-term genetic threat represented by any long-lived radioisotope utilises a quantity known as dose commitment, obtained *via* integration of dose over that time during which there is a significant contribution to the world population. For bomb ^{14}C , the dose commitment as calculated by UNSCEAR is 140 mrad and 170 mrad to soft tissue/bone marrow and bone-lining cells respectively³. These totals overestimate the potential radiation hazard from bomb ^{14}C , however, by total neglect of the Suess effect which, in the absence of artificial production of ^{14}C , would be expressed as a decrease in the tropospheric ^{14}C activity of ~40% below the natural level. Total accumulated doses in this article are obtained by addition of all annual absorbed doses in excess of that delivered by natural ^{14}C . Such a summation is performed until 2050 for bone-lining cells and to 2035 for soft tissue/bone marrow (see Fig. 2) to give values of 10 mrad and 8.5 mrad respectively. These totals, though well below ^{14}C dose commitments of the UNSCEAR report, are, we feel, more relevant for discussion of the real human radiation burden from bomb ^{14}C .

Table 1 Accumulated absorbed doses due to bomb ^{14}C

Period under consideration	Accumulated dose (mrad)	
	Soft tissue/bone marrow	Bone-lining cells
pre 1954	—	—
1955–1984	7.26	3.16
1964–1993	8.81*	4.95
1970–1999	8.31	5.69
1985–2014	6.65	6.57*
1965–2024	bone growth during initial 20 yr	24.80* (60-yr dose)

*Maximum doses.

Assessment of the human radiation burden from bomb ^{14}C is the aim of this paper; thus it is important to relate the quantities determined here, which belong obviously in the category of low radiation doses to cellular modification, particularly chromosomal DNA damage. Possible radiation-induced chemical changes which occur in DNA have been reviewed recently¹¹ while Table 2 indicates the probability of damage per rad to DNA and other genetic components of a cell. Information in column 3, applicable to bomb ^{14}C , should be regarded with caution since data in column 2 are compiled from numerous research projects performed under a diversity of experimental conditions—dose rate, type of irradiation, but notably, type of cell¹². On the other hand, results of recent experiments using ^{14}C -methyl thymidine incorporated in mammalian DNA, substantiate at least the quoted extent of single strand breakage¹³. Allowance is made in Table 2 for repair of single strand breaks (up to 85% in mammalian DNA¹⁴) especially since such repair has also been shown to result in normal replication¹⁵. Unfortunately, interpretation of probabilities of cell damage due to bomb ^{14}C remains difficult since the lesion(s) responsible for the visible expression of biological damage has yet to be identified. For example, if each chromosome break is a critical lesion, the total absorbed dose due to bomb ^{14}C implies an ultimate probability of damage to any cell of 2×10^{-3} to 10^{-4} . Thus, given a birth rate of 3% in a world population of 2.5×10^9 , 1,500–7,500 offspring would possess altered genetic material resulting in a wide range of consequences.

Table 2 Estimates of biological damage to reproductive cells from ^{14}C β -irradiation (30-yr accumulated dose)

Description of damage to genetic material	Extent of damage (probability per cell)	
	Typical values per rad of ionising radiation	Contribution from bomb ^{14}C β -irradiation*
Single-strand breaks	10	0.01†
Double-strand breaks	1	0.006
Chromatid breaks	0.002–0.24	1.2×10^{-6} – 1.4×10^{-3}
Chromosome breaks	0.002–0.01	1.2×10^{-6} – 0.6×10^{-4}
Damaged bases	5–15	0.03–0.09

*Calculations performed using maximum bomb ^{14}C 30-yr absorbed dose.

†Probability based on 85% repair of single-strand breaks.

Local effects from the $^{14}\text{C} \rightarrow ^{14}\text{N}$ transition involve possible consequences of nuclear recoil, excited electronic state, and modified valence state of the daughter nucleus. In each respect, exact location of a ^{14}C atom is expected to be critical; and in certain situations, the transmutation effect may be the dominant damage factor. On the other hand, distinction between consequences of β -irradiation and local events is difficult for such a low-energy β -particle. Consequently there is conflicting experimental evidence for and against a positive transmutation role of ^{14}C decay⁴. Long-term experiments involving a ^{14}C general labelling technique have been completed recently by Lee and co-workers¹⁷; although genetic damage could be attributed to β -irradiation effects alone, the possibility of a transmutation effect associated with specifically-labelled DNA was not dismissed. With this background of inconclusive experimental evidence, the approach of Totter *et al.*⁷ remains the best theoretical treatment of a transmutation role during ^{14}C decay. Two situations for bomb ^{14}C are considered, (1) transmutation=mutation, cf. Totter *et al.*, and (2) transmutation at only one type of carbon site in DNA=mutation. Resultant values (see Table 3) represent extreme cases of a potential transmutation effect; once again, visible expression of this damage to cellular components cannot be predicted.

Table 3 Theoretical assessment of the transmutation effect of ^{14}C (applied to bomb ^{14}C)

total dose to gonads from bomb ^{14}C $\approx$ 10 mrad	
time span involved = 80 yr	
thus mean annual dose to gonads (bomb ^{14}C) = 0.13 mrad	
cf. annual dose to gonads (natural ^{14}C) = 0.68 mrad	
dose rate due to bomb ^{14}C is $\approx$ 20% that due to natural ^{14}C	
disintegration rate of natural ^{14}C = 13.56 d.p.m. g^{-1} carbon	
wt of DNA per cell $\approx$ 8.6×10^{-13} g	
% of carbon in DNA $\approx$ 37%	
therefore no. of ^{14}C d.p.m. $\approx$ $13.56 \times 8.6 \times 10^{-13} \times 0.37$ per DNA per cell	
decays per DNA per cell per yr (natural ^{14}C) $\approx$ $13.56 \times 60 \times 24 \times 365 \times 8.6 \times 10^{-13} \times 0.37$	
$\approx$ 2.27×10^{-6} decays per cell per yr	
decays per DNA per cell per yr (bomb ^{14}C) $\approx$ $\frac{2.27 \times 10^{-6}}{5}$ decays per cell per yr	
$\approx$ 4.5×10^{-8} decays per cell per yr	
Case 1	
transmutation = mutation, thus probability of mutation	
$= 4.5 \times 10^{-8}$ per cell per yr	
birth rate $\approx$ 3%	
world population $\approx$ 2.5×10^9	
total no. of yr = 80	
total offspring affected $\approx$ 27,000	
Case 2	
transmutation at only one type of carbon site is responsible for a mutation, thus probability of mutation	
$= \frac{4.5 \times 10^{-8}}{40}$ per cell per yr*	
total offspring affected $\approx$ 700	

*Approximately 40 different carbon sites in DNA.

Owing to their obvious limitations, the preceding approaches can only represent crude attempts at assessment of genetic damage due to bomb ^{14}C . For more relevant consideration of the social implications of artificial production of this radionuclide, reference is made to the latest UNSCEAR report which contains risk estimates of radiation-induced genetic disorders in humans³⁰. These data are calculated with respect to damage to spermatogonia and oocytes, the germ cells most at risk, and are based on expected rates of damage at low doses and in conditions of chronic exposure, particularly applicable to ^{14}C . In the report, two approaches are employed to determine incidences of mutation of the zygotes—formed by union of male and female germ cells—per rad of low-dose irradiation administered to the parental generation. First, an incidence of damage of $\sim 1,500$ per 10^6 spermatogonia is obtained by extrapolation of genetic data involving mice to humans, taking into account the 20% increase in size of the human genome. The second value, 300 per 10^6 spermatogonia, is derived using a 3% spontaneous incidence in genetic damage among live born, together with a radiation doubling dose of 100 rads—that low-dose irradiation expected to double the natural mutation rate. Corresponding radiation damage to oocytes is considered negligible in comparison. Combination of these incidences of damage with 10 mrad, the total absorbed dose to the gonads due to bomb ^{14}C , yields upper and lower limits of 1,125 and 225 respectively for the number of individuals who will possess severe deleterious traits attributable to this radioisotope. It should be stressed that these figures have been derived using a linear dose-response relationship extrapolated to those levels of bomb ^{14}C , and should be assessed accordingly. Expression of this damage in first generation offspring is estimated at ~ 20 – $55/5$ –10 using an assumed range of dominance in man of 2%–5%³¹. Consideration of minor deleterious effects have not been included in this computation but are expected to be more abundant even if no visible damage is apparent. This fact explains to some extent the lower values obtained here compared with those calculated in the preceding analyses.

With respect to late somatic effects, in particular an increase in number of leukaemia and cancer/tumour victims from effects of ^{14}C decay, there is a similar lack of data obtained at low doses and under chronic exposure conditions. Again, a linear dose-response relationship is assumed for radiation burden assessment although there is

evidence of a sigmoid relationship for low-density ionising radiation¹⁸. Spiers¹⁹ uses a figure of 100 cases per 10^6 individuals per rad as the total risk of leukaemia and different types of bone tumours; this induction rate is derived from the UNSCEAR report³² and is rounded off owing to the many uncertainties involving dose-effect data. Thus this incidence of damage corresponds to a total of $\sim 2,000$ cases attributable to bomb ^{14}C ; again the role of transmutation of ^{14}C may be significant but this topic has been discussed recently by Tamers²⁰.

For both genetic and somatic considerations, the potential human radiation burden due to artificially produced ^{14}C and calculated using the assumptions stated is certainly significant and, therefore, cannot be dismissed. However, relative to the world population and in view of the time span over which this dose is delivered, some three to four generations, the conclusion of this study must be that such effects will occur unnoticed.

Bomb ^{14}C as a biological tracer

THE release of ^{14}C in nuclear explosions, particularly those detonated in 1961–1962, has caused a major disturbance of the steady-state natural distribution of this radioisotope. The resultant pulse of bomb ^{14}C , detected initially in the atmosphere, has since been used extensively in evaluation of rates of exchange of carbon between major reservoirs of the dynamic cycle — notably atmospheric CO_2 and ocean water bicarbonate^{1–7}. Within the biosphere, however, investigation of human ^{14}C levels has been more limited despite the application of bomb ^{14}C as early as 1959 by Broecker and co-workers⁸ in the determination of residence times of carbon in several tissues. Perhaps the most specific result to emerge from initial research on this topic was the demonstration of almost total inertness of collagen in the adult human skeleton as evidenced by its failure to incorporate significant amounts of artificial ^{14}C (ref. 9). In other related ^{14}C measurements^{10–13}, a non-correspondence between contemporary human and atmospheric ^{14}C levels was often observed. Nydal and co-workers proposed a combination of three factors to account for such variations¹³ and concluded from a long term analysis of ^{14}C concentrations in human blood and hair samples that bomb ^{14}C enters the human body 1.4 years after production in the atmosphere, and remains there with a mean lifetime of 10 years. This article describes the continuation at Glasgow of an intensive investigation of the presence of bomb ^{14}C in humans, initiated by Harkness and Walton¹². Comparison by these workers of blood plasma protein ^{14}C data with predicted dietary ^{14}C levels¹⁴ has confirmed that a finite turnover of carbon in the human body does exist. Here, determination of ^{14}C activities of atmospheric CO_2 , dietary and human tissue samples enables a more detailed evaluation of residence times.

Atmospheric CO_2 was sampled monthly by adsorption in KOH solution (4 M) at three UK locations (see Fig. 1). Representative samples from each location were analysed for ^{14}C content since ^{14}C measurement of all samples was impracticable. Human tissues, normally about 20 g, were obtained unfixed from postmortem examinations. After washing, the tissues were homogenised and freeze-dried and subsequently samples were combusted directly to CO_2 or pretreated, before combustion, with Bloor's solvent (ethanol-diethyl ether, 3:1 v/v) to provide protein- and lipid-rich components for analysis.

Grossly diseased aortas from victims of atherosclerosis were forwarded from New Orleans, USA. An additional artery sample was obtained at Glasgow. Although the former samples had been stored in formalin, it was felt that this source of carbon contamination would be eliminated during lipid extraction. After washing, the intima was carefully stripped from the other two arterial layers; plaques were separated from relatively normal tissue and extracted overnight at room temperature with chloroform-methanol (2:1 v/v). The extract yielded on evaporation an oil from which lipids were selectively removed into ether-hexane (1:1 v/v). This solution was washed with warm saline solution, dried with Na_2SO_4 , and evaporated to dryness. A stream of nitrogen was passed over each residue for several hours to ensure total removal of solvent. Samples obtained in this way weighed typically 1–2 g.

Biological samples were combusted in a stream of oxygen and the resultant CO_2 absorbed in KOH solution. Details are given elsewhere¹⁵ of the subsequent purification of CO_2 necessary for gas-proportional anti coincidence counting. ^{14}C activities were measured in a 2.61 counter, filled to a pressure corresponding to one atmosphere at 15 °C; under these conditions the background count rate was 4.9 c.p.m. with an observed deviation of -0.01 c.p.m. per mbar rise in atmospheric pressure.

Tables 1 and 2 include the ^{14}C results of all human tissues analysed, after correction for isotopic fractionation by analysis of the $^{13}\text{C}/^{12}\text{C}$ ratio of each sample relative to the P.D.B. Chicago Limestone Standard. Corresponding theoretically

Fig. 1 Environmental ^{14}C concentrations, 1953–1973. ●, Fish samples obtained fresh in March 1973 (●P = plaice); M, meat obtained fresh in January 1972. —, N. Hemisphere troposphere; ---, S. Hemisphere troposphere., Mixed ocean layer; — · —, computed dietary level. Inset: $^{14}\text{CO}_2$ activities at UK latitudes, —●—, Lerwick (60°08'N, 01°11'W); —□—, Snowdon (53°03'N, 04°00'W); —×—, Chilton (51°31'N, 01°20'W).

determined values were evaluated by application of a suitable box-model treatment of carbon turnover in tissues. The potential of bomb ^{14}C in this system results from nature's unique labelling mechanism whereby ^{14}C incorporation in biological material yields a uniform distribution throughout each molecule—no particular molecular sites are favoured. ^{14}C , both natural and man-made, is assimilated by plants by photosynthesis with subsequent transfer to humans through the food chain. Thus the ^{14}C content of any tissue may be regarded as a function of dietary ^{14}C level and of the residence time of carbon in that tissue. From this basic model (Fig. 2a) it can be shown that, for adult tissue, in which an essentially stationary state exists (carbon input = output), the ^{14}C content at any time is given by the equation (see a similar expression by Jansen¹⁶)

$$\Delta_T^{nt} = \Delta_T^0 + \sum_{i=1}^n \left\{ \Delta_D^{ni} - \Delta_T^{(n-1)i} \right\} \left\{ 1 - \exp(-k_T i) \right\} \quad (1)$$

where T and D refer to tissue and diet respectively; $\tau = 1/k_T$, the mean residence/turnover time, is the average time required by a tissue for replacement of an amount of carbon equivalent to the tissue itself. Thus for a given τ value, and with i fixed at 0.5 yr, tissue ^{14}C concentration is dependent only on the cumulative differences between the previous ^{14}C activity and the mean ^{14}C content of the diet over the subsequent half-yearly interval. By appropriate choice of zero time (t_0 before the effects of nuclear weapon tests) a plot of Δ_T^{nt} against nt indicates build-up of bomb ^{14}C in any tissue.

*These data are described in greater detail in refs 15 and 16.

†Age and sex of donor, month and year of death are given.

P, protein-rich; L, lipid-rich; mf, marrow fat; col, collagen; muscle analysed, forearm. See also footnotes to Table 2.

In practice, dietary ^{14}C content has not been measured with sufficient frequency over the last 20 yr but may be related to two more adequately monitored systems—atmospheric CO_2 and ocean carbonate/bicarbonate. Many such correlations are well established: plant life and cereals are good indicators of ambient atmospheric ^{14}C activities^{19,20}. In addition, the food types included in Fig. 1 reflect, fairly closely, environments of their origin, although recognition must be given to existence of carbon turnover in animals as well as in humans. Further relationships used in this study have been derived from previous environmental ^{14}C measurements²¹ coupled with data on stock/production of foodstuffs; the latter allows assessment of lag times between food growth and consumption (see Table 3).

With this knowledge, a comprehensive survey of dietary habits of the UK population was performed to evaluate

percentages of protein, lipid and carbohydrate supplied by different commodities. Note was made of the hemisphere of origin of food imports since marked disequilibrium between north and south hemisphere tropospheric CO_2 activities existed until 1971. The mean ^{14}C content of a typical UK diet

Fig. 2 Single compartment models of carbon turnover. X turns over with rate constant k_X , that fraction of X replaced in unit time (1 yr). X represents in (a), tissue carbon, supplied by a dietary source only; and in (b), arterial lipid carbon, supplied by the blood by material of dietary and endogenous origins. $\Delta_T^0 = ^{14}\text{C}$ content of tissue at t_0 , computed zero time; $\Delta_T^{ni} = ^{14}\text{C}$ content of tissue ni years after t_0 ; i is a suitable time increment—0.5 yr; $\Delta_D^{ni} = \text{mean } ^{14}\text{C}$ content of diet over the n^{th} i period after t_0 . For the non-stationary system: $N^{ni} = \text{no. of carbon atoms } ni \text{ yr after } t_0$ (tissue/lipid); $N_T^0 = \text{no. of carbon atoms at } t_0$ —at birth/11 yr of age.

at any time (see Fig. 1) is given by the expression

$$\Delta_D^{ni} = 0.24\Delta_{\text{TN}}^{ni} + 0.19\Delta_{\text{TN}}^{(n-1)i} + 0.16\Delta_{\text{TN}}^{(n-2)i} + 0.28\Delta_{\text{TN}}^J + 0.02\Delta_{\text{TS}}^{ni} + 0.035\Delta_{\text{TS}}^{(n-2)i} + 0.035\Delta_{\text{TS}}^J + 0.04\Delta_{\text{M}}^{ni}$$

TN and TS signify north and south hemisphere tropospheres respectively, while M denotes the mixed surface-ocean layer; $(n-1)i$ and $(n-2)i$ denote lag-time effects and J refers to the preceding period of maximum photosynthesis.

For tissues under growth, non-stationary conditions necessitate a modified approach. Use is made here of the general shape of growth curve obtained for most tissues²²; this curve, to a first approximation, may be regarded as a combination

Table 2 ^{14}C content of human tissue

Donor	Sample	$\Delta(\%) \pm 1\sigma$
M/66: 3/73	Liver (normal)	50.0±0.9

M/67: 1964	Intimal lipid	9.7±0.9
M/69: 1964	Intimal lipid	17.9±0.8
F/86: 6/73	Intimal lipid	47.1±0.9
	Adventitia	31.6±0.8

*Normally, sample activities are quoted initially as $\delta^{14}\text{C}$, the per mil enrichment over $0.95 \times \text{NBS Oxalic Acid Standard activity}$ (=1890 wood). Here, after correction for isotopic fractionation using the Lamont VIII formula¹⁷, final values, expressed as $\Delta(\%)$, are shown in column 3. ^{14}C concentrations defined on this scale can be regarded as the percent deviation from pre-bomb or natural levels; $\Delta = 0\%$ corresponds to a natural ^{14}C concentration, and $\Delta = 50\%$ to a concentration $1.5 \times$ natural level. Errors, arising from uncertainties in ^{14}C activity measurement only, are quoted to one standard deviation ($\pm 1\sigma$).

Table 3 Dietary information

Main food categories	Contribution to typical diet (%)	Environmental relationship, Δ_D^{ni}
Milk/dairy products	23.0	Δ_T^{ni}
Cereals/flour/sugar	31.5	Δ_T^{ni}
Meat/poultry	34.0	$\Delta_T^{(n-1)i}, \Delta_T^{(n-2)i}$
Fruit/vegetables—fresh	3.4	Δ_T^{ni}
—other	3.7	$\Delta_T^{(n-1)i}$
Fish	4.4	Δ_M^{ni}

of two linear growth periods: from birth to 11 yr, and from 11 to 20 yr. In these conditions the comparable equation is

$$\Delta_T^{ni} = \Delta_T^0 + \sum_{n=1}^i \left\{ 1 - \frac{N_T^{0+}(n-1)(N_T^i - N_T^0)}{N_T^{ni}} \exp(-k_T i) \right\} \times \left\{ \Delta_D^{ni} - \Delta_T^{(n-1)i} \right\} \quad (2)$$

Since the first 2 yr after birth are best expressed by an exponential growth function, N_T^0 , rather than the absolute number of carbon atoms at birth, is that value obtained by extrapolation to birth (t_0) of the linear section of growth. Both N_T^0 and $N_T^i - N_T^0$, the increment in number of carbon atoms per 'i' time period, may be expressed as fractions of the mature tissue. For the 5-yr-old tissue series, errors involved in basic assumptions of the non-stationary system are considered too great to justify such a treatment. Nevertheless, ^{14}C activities of this series, with the exception of one organ, reflect dietary ^{14}C levels of the 18-month period prior to analysis. The different dietary pattern of a child may be responsible for the observed low ^{14}C content of spleen.

Model treatment of lipid accumulation in arteries also

Fig. 3 Predicted ^{14}C content of mature tissues, 1953–1973. Each curve represents a different mean residence time of tissue carbon. Steady-state conditions and first-order kinetics of carbon turnover are assumed to exist. —●—; $\tau = i$ yr; —D—; $\tau = 0$.

involves a non-stationary system. Numerous pathological findings indicate a linear incidence in number of atherosclerotic lesions with time from 20–25 years of age²³. Thus on the basis of a corresponding increase in amount of carbon deposited, the corresponding version of equation (2) is:

$$\Delta_L^{ni} = \Delta_L^{(n-1)i} + \sum_{n=2}^i \left\{ 1 - \frac{(n-1)}{n} \exp(-k_L i) \right\} \times \left\{ \Delta_L^{ni} - \Delta_S^{(n-1)i} \right\} \quad (3)$$

where L and S refer to lipid and source carbon respectively the latter is taken to be of composition similar to that of

Fig. 4 Predicted ^{14}C content of tissues under growth, 1953–1973. Non steady-state conditions exist: (a) The general series of curves was based on two linear growth periods—birth–11 yr, and 11–20 yr. (b) For brain tissue, curves were computed for linear growth from birth–5 yr; thereafter steady-state conditions were applied. (c) For reproductive tissue, equation (1) was applied from birth to 15 yr, followed by linear growth from 15–20 yr. —●—; $\tau = i$ yr.

corresponding lipids in blood—30% dietary and 70% endogenous origins²⁴. Although most tissues are capable of preparation of cholesterol and its esters, two major components of the arterial extract, liver and gastrointestinal tract are considered to be main sites for biosynthesis of these fractions²⁵. Thus each Δ_S term is subdivided as follows:

$$\Delta_S^{ni} = 0.3\Delta_{D_2}^{ni} + 0.7\Delta_T^{ni}$$

Δ_T^{ni} data were obtained from estimated ^{14}C activities of a relevant tissue such as liver, while dietary emphasis was placed on those constituents high in cholesterol, total fat, and saturated fatty acid content; in this case

$$\Delta_{D_2}^{ni} = 0.48\Delta_{TN}^{ni} + 0.09\Delta_{TN}^{(n-1)i} + 0.28\Delta_{TN}^{(n-2)i} + 0.095\Delta_{TS}^{ni} + 0.035\Delta_{TS}^{(n-2)i} + 0.02\Delta_M^{ni} \quad (4)$$

Figures 3–5 contain series of curves computed from Δ_D^{ni} input relevant to each model, each curve corresponding to a

Fig. 5 Predicted ^{14}C content of arterial lipid deposits, 1953–1973. A similar situation to Fig. 4 exists, but with a different source of carbon input (30% dietary, 70% endogenous). No deposit was present at zero time, t_0 . —●—: $\tau = i$ yr; —○—: $\tau = 0$.

different mean residence time of tissue carbon. Comparison of the contents of Table 1 with the relevant figure yielded estimates of the turnover time, τ years, of carbon in that tissue. Uncertainties in this comparison are related to (1) ^{14}C activity measurement ($\pm 1\sigma$) and (2) diet-atmosphere relationship (estimated at ± 1 yr). Figure 3 shows that, for τ values 0–5, uncertainty in the diet-atmosphere relationships is predominant, while for longer residence times, both (1) and (2) are equally significant. Thus sensitivity of the bomb ^{14}C tracer method is expressed in terms of years rather than months. At this level of resolution, differences in turnover rates of normal against cancerous tissue are undetectable, certainly at the time of sampling. Similarly, for the purposes of this study, protein, lipid and whole tissue carbon exhibit no significant τ value variation. On the other hand, the long residence time obtained for bone collagen confirms previous findings^{9,14} of comparative inertness of skeletal carbon relative to soft tissue.

Significant variations in τ values exist, not only in tissues of

one donor, but also between the same tissues in different individuals, with no apparent trends as a function of age. Of the soft tissues, only thyroid carbon can be assigned, with confidence, a residence time ≥ 9 yr; elsewhere, in many cases, choices of τ values/range of τ values exist. This ambiguity does not imply that both selections are possible but merely signifies the inability of the model to distinguish between certain residence times owing to the proximity, at the time of analysis, of certain curves. However, it is difficult to reconcile the smaller of two choices of τ with the number of tissues ($> 25\%$) in which a residence time ≥ 8 yr is indicated. Comparison of Figs 3 and 4 shows that, for $\tau = 0/1$, there is negligible difference between corresponding Δ_T curves; yet about 35% of both 21-yr-old tissue series have ^{14}C content higher than either corresponding data from contemporary donors, or Δ_D values at the period of sampling. Considered together, these tissue results imply a residence time > 0 , but typically 2–5 yr. Thus as shown in Table 4, preference is given to upper τ ranges. In view of limitations imposed on the model at this time, a representative value of the mean turnover time of soft tissue carbon is taken as 6 ± 4 yr. This figure must be regarded as a maximum estimate which includes recycling of carbon within a tissue as well as interaction between different organs. Obviously the advantage of the bomb ^{14}C approach lies in detection of slow turnovers, typically > 6 yr; results can then be used to complement short term tracer studies which often fail to establish accurate upper limits on turnover rates. It should be stressed that τ values determined here are representative of each tissue in its entirety, or at least of its protein-lipid fractions. Extreme variations in metabolic rates must exist within tissues then, if results of this study are considered in conjunction with previous experimental observations which indicate much faster turnover rates of tissue amino acids^{26,27}.

Further application of bomb ^{14}C as a biological tracer is illustrated by Table 5 which implies a residence time, for carbon in intimal lipid deposits, of at least 5 yr. In the context of the model used, however, $\tau > 10$ yr seems more probable, provided that lipid is deposited directly from the blood. Another possible mechanism of lipid accumulation—*in situ* production—has been proposed²⁸, particularly for phospholipid build-up; accordingly, low Δ_L values may reflect ^{14}C activities of the endogenous precursor(s) of deposited carbon. In this respect, the ^{14}C content of adventitia (outer arterial layer) indicates the presence of about 25% natural ^{14}C , probably attributable to collagen²⁹. These data, while insufficient for detailed interpretation, encourage further measurements along a similar theme to determine the possible pathogenesis or timescale of treatment of atherosclerosis.

Lunar cycle and timing of mating season in Serengeti wildebeest

WILDEBEEST (*Connochaetes taurinus* Thomas) herds numbering nearly 1 million (refs 1, 2) on the Serengeti Plains, Tanzania, produce about 80% of their young during a 3-week period in January or February³. This is short compared with the 2-month birth period of the wildebeest in South Africa⁴, or to the 3-4-month birth period of buffalo and other grazers in the Serengeti⁵. A suggested advantage for the closely synchronised wildebeest birth period is that it reduces the probability of hyaena (*Crocuta crocuta* Erxleben) predation on the young^{3,6-8}. I report here evidence which suggests that the lunar cycle is the external timer for the synchronisation.

I have calculated individual conception dates from records of (1) foetus weights collected randomly and (2)

birth dates. Conception date can be calculated from foetus weight (ref. 9) (Fig. 1), and from birth date with a known gestation length. This lies between 8 and 9 months (refs 10, 11) and I have assumed 255 d.

Figure 1 shows the frequency distribution of conception dates from a random sample of 33 foetuses collected in 1971. Also shown are conception dates for 1964 and 1965, and the mating period for 1962 and 1963, all of which were calculated from information given by Watson¹¹. The distribution of conception dates for 1964, 1965 and 1971, together with other evidence³, show that conceptions are synchronised into one discrete time period with a relatively sharp onset. I have called this the 'mating period'.

Fig. 1 Distribution of wildebeest conception dates in different years. Full moon is indicated by arrows. Conception dates were obtained from the relation between foetus age in days (t) and its weight in grams (W): $W^{1/3} = a(t - t_0)$, where t_0 is 20% of gestation length (t_g) and equals 51 d. 'a' is a growth constant and equals $W_g^{1/3}(t_g - t_0) = 0.143$. W_g is the birth weight of 25 kg. For the few small foetuses under 100 g, age was calculated directly from growth curves extrapolated from cattle¹³.

In Fig. 1 the times of full moon are shown by arrows. The mating period, where adequately observed (1962-1965, 1971), falls between the full moons. It starts approximately at the full moon and covers the new moon period. If there was no association between the timing of the mating period and the occurrence of full moon, the latter would be expected in the middle of this mating period on some occasions. To test for such an association I compared the starting date of the mating period with the date of the nearest full moon (Table 1), for there is additional information on the starting date derived from calving in the years 1968 and 1972 in a population 50 km to the east in Ngorongoro Crater, and also in the Serengeti in 1973 (A. and J. Root, personal communication). Estes⁹ observed the calving in three discrete herds in Ngorongoro in 1973.

If there was no relation between starting date and full moon then these dates should fall randomly within 15 d

Table 1 Absolute difference between full moon and start of the mating period

Place	Year	Start of mating period	Full moon	Difference between start and full moon (d)
Serengeti	1962	20 April	19 April	1
Serengeti	1963	7 May	8 May	1
Serengeti	1964	25 April	26 April	1
Serengeti	1965	16 May	14 May	2
Ngorongoro	1967	21 May	23 May	2
Ngorongoro	1971	15 May	10 May	5
Serengeti	1971	20 May	10 May	10
Ngorongoro a	1972	25-27 April	28 April	3
b	1972	25-27 April	28 April	3
c	1972	25-27 April	28 April	3
Serengeti	1972	27 April	28 April	1

either side of any full moon. Table 1 shows that 10 of the 11 dates fall within 7 d and 9 fall within 5 d of the full moon, strongly suggesting a relationship (the latter figures have $\chi^2=7.25$ with Yates correction, d.f.=1, $P<0.01$).

Supporting evidence for this relationship comes from the dates when first calves were observed by the park warden M. Turner¹² in the years 1956–1965. Conception dates have been calculated from these (Table 2). If there was no relationship with the moon, then these dates should fall at any time during the 30 d since the preceding full moon. In fact in eight out of ten years the first calculated conception fell within the first 10 d following the full moon, and all fell within the first 15 d ($P<0.01$, Kolmogorov-Smirnov test¹³). Wildebeest can delay birth for a short time⁸ but not to the extent that it could have produced the above observations.

Table 2 Conception dates calculated from first observed calving dates

First observed calving date	Conception date	Time since full moon (d)
11 November 1956	29 February 1956	4
4 December 1957	25 March 1957	10
16 December 1958	5 April 1958	2
6 December 1959	27 March 1959	3
2 December 1960	23 March 1960	11
20 December 1961	9 April 1961	9
12 November 1962	1 March 1962	9
27 October 1963	13 February 1963	5
23 November 1964	12 March 1964	14
28 December 1965	17 April 1965	2

All conception dates have been calculated using the mean gestation length of 255 d. This may be 5–10 d shorter or longer. Consequently until gestation time is more accurately known, one cannot say which lunar phase is important, but only that some aspect of it, as yet undetermined, is influencing conception.

Figure 1 shows that conceptions take place at approximately the same time each year. For conceptions to occur only in the lunar cycles of April and May an external variable showing an annual rhythm must also be influencing the animals. Although at this latitude (3°S) day-length alters by only 20 min through the year and is changing at its slowest in May (Fig. 2), it is possible that a combination of photoperiod and lunar cycle may act to trigger mating.

Alternatively local climatic conditions could act as a trigger for they are changing markedly at the start of mating in April (Fig. 2). In particular, rainfall and the amount of green grass upon which the animals feed¹⁴ decline rapidly at this time. This hypothesis is illustrated in Fig. 3. When rainfall or some related factor such as

Fig. 2 The birth and mating season of Serengeti wildebeest in relation to daylength (●), mean monthly rainfall 1963–1972 (■), and % crude protein in the diet in 1971 (▲).

Fig. 3 Suggested model for the synchronisation of conceptions in wildebeest. When the climatic cycle (rain, food) falls below a threshold the animals become sensitive to the lunar cycle which switches on ovulation or allows conception to occur.

nutritional intake falls below a certain threshold, then the animals may become sensitive to changes in the lunar cycle. This still leaves a choice of two or three cycles to choose from. It is possible that if all females conceive in the first lunar cycle after the beginning of the decline in rainfall, then no conceptions would be observed in the following potentially suitable cycles. Indeed the birth data of Estes¹ in Ngorongoro show that some but not all small herds mate over a 2-month period, the distribution of conceptions being bimodal, with each peak coincident with each new moon. The data indicate that if the full moon occurs in the first half of April then conceptions are delayed by one more lunar cycle. These hypotheses can be tested by making predictions on the timing of the mating and birth seasons for future years.

To my knowledge this is the first case of a strong relationship between conception and the lunar cycle in mammals. There may be a similar effect in Australian water-buffalo (*Bubalus bubalis*)¹⁴ and perhaps a small effect on man¹⁵. For other mammals the data remain inconclusive¹⁶. The effect of lunar cycles may still be of relevance to the timing of breeding seasons in tropical regions, however.

Passage of *Trypanosoma brucei rhodesiense* through the peritrophic membrane of *Glossina morsitans morsitans*

THE developmental cycle of African sleeping sickness trypanosomes in tsetse flies (*Glossina* spp.) as described by Robertson¹ has recently been questioned², especially the route whereby trypanosomes get from within the mid-gut of the fly to the salivary glands, where they develop into forms capable of infecting fresh mammalian hosts. We have shown² that trypanosomes developing in the mid-gut of *Glossina morsitans morsitans*, which are usually regarded as possessing low penetrative powers, are able to penetrate and pass through the gut cells of the fly. We present here more evidence of the penetrative powers of the fly mid-gut forms of *Trypanosoma brucei rhodesiense*—penetration of the peritrophic membrane of *G. m. morsitans* before their penetration of the gut cells.

An essential part of the developmental cycle of *T. brucei* spp. trypanosomes in the fly is the passage of the trypanosomes from the endoperitrophic space of the midgut to the ectoperitrophic space. The traditionally accepted route for this passage¹ is for the trypanosomes to escape from the confines of the peritrophic membrane around its often ragged posterior ends, where the mid- and hindgut join, and so gain access to the ectoperitrophic space. It has been suggested that trypanosomes *en route* to the salivary glands have to re-enter the endoperitrophic space by penetrating

the peritrophic membrane in the region of the proventriculus. Here the membrane is freshly secreted and hence soft^{3,4}, and electron micrographs of trypanosomes penetrating the peritrophic membrane in this region have been published⁵. This portion of the peritrophic membrane has also been suggested as a possible site for the initial access of the trypanosomes to the ectoperitrophic space^{6,7}. The penetration we describe, however, takes place in the middle section of the mid-gut, halfway between the proventriculus and the junction of the mid- and hindgut.

The techniques for the preparation of infected blood meals, the feeding, details of infecting trypanosomes and dissection of the flies, together with those for fixation and EM examination, were as used previously². Throughout our studies of this model, flies not sacrificed continued to harbour trypanosomes, and a satisfactory proportion developed mature salivary-gland infections and transmitted the infection to new mammalian hosts.

We found that as digestion of the infected blood meal proceeds and the volume of the material within the peritrophic sac diminishes, the peritrophic membrane becomes thrown into folds, and pockets are formed which trap the trypanosomes (Fig. 1a). The peritrophic membrane probably has several layers, the most easily recognisable of these being an inner osmophilic layer and an outer, paler, wider and more diffuse one. These layers separate (Fig. 1b) and the trypanosomes penetrate the osmophilic layer and gain entry to the space between the separated layers of the membrane (Fig. 1c). Penetration takes place most commonly at the apex of the membrane folds, which is the site

Fig. 1a A trypanosome trapped in a fold of the peritrophic membrane; note the 'buckling' of the inner layer at the apex (arrowed). b, Separation of the peritrophic membrane layers. c, Two trypanosomes lying between layers of the membrane in a fold. d, A trypanosome lying within the outer thicker layer. The cells of the blood meal (RBC) are below the peritrophic membrane. Bars represent 1 μ m.

where the separation of the layers is most frequently seen, particularly where the osmophilic layer is on the inside of the curve. Figure 1d shows trypanosomes lying within the thick layer of the peritrophic membrane.

Penetration of the peritrophic membrane occurred throughout the central two-thirds of the midgut, and its frequency was related to the trypanosome concentration, which was greatest in these central sections. We found no evidence of penetration occurring in the hindmost portion of the midgut, and the few trypanosomes found at this level appeared moribund. Nor did we find trypanosomes involved in the peritrophic membrane anterior to this midgut region. If any trypanosomes initially entered the ectoperitrophic space through the soft membrane in the proventricular region⁵ they had disappeared within 70 h of the infected feed, and we found no evidence of any trypanosomes outside the membrane until 10 d had elapsed.

Nine days after an infected feed all the trypanosomes were still within the peritrophic sac; by 11 days most of the trypanosomes had passed to the ectoperitrophic space, only 5% remaining within the sac, and a similar proportion were still involved in active penetration. The passage of successive waves of trypanosomes across the membrane from additional infected feeds took less time to complete—12 d compared with 14 d for a single infected feed.

The peritrophic membrane was found to be separated into two layers only in the presence of trypanosomes. Digestive enzymes may have a role in this process, but difference in rigidity between the layers of the membrane could certainly account for the separation seen at the sharp folds which occur when the sac contents decrease during the digestion of a blood meal. Lehan⁶ has shown in *Stomoxys calcitrans* that the thin layer of the peritrophic membrane contains no chitin (a rigid material) while the underlying layer does.

Epidemiological studies of the vectors of African sleeping sickness have traditionally relied on examination of the tsetse fly salivary glands for evidence of infection. In areas of endemic disease, the infection rates recorded by this method often fail to reach 0.8% (ref. 9). Any alternative life-cycle pathways of trypanosomes within the vector might suggest additional sites to examine within the fly when looking in the field for potential transmitters of African trypanosomiasis. Are we at present overlooking a large number of tsetse flies already capable of transmitting disease by only examining the salivary glands? Are the salivary glands continuously primed with trypanosomes coming from other parts of the fly (the haemocoel for instance) so as to maintain the population of metacyclic trypanosomes; or, once primed, is this sufficient to maintain salivary gland infection for the rest of the life of the fly? These are fundamental questions which a detailed study of all stages of the life-cycle of the trypanosomes in the fly would resolve.

Rhodopsin content and electroretinographic sensitivity in light-damaged rat retina

EXPOSURE of rats to continuous illumination leads to cellular deterioration within the retina and a concurrent reduction of electroretinogram (ERG) responses^{1,2}. Grignolo *et al.*³ showed that at early stages, this 'damage' due to light is hypertrophic in that tubules and vesiculae appear in receptor cell outer segments. They surmised that losses in retinal functioning are initially due to disorganisation rather than degeneration. But, experiments on recovery from light damage⁴ indicate that ERG sensitivity returns as the rhodopsin-containing disks of the outer segments are regenerated even though their original lamellar structure is not restored. It is thereby implied that as long as visual pigment is present at functional sites, the normal structure of the outer segments may not be crucial to ERG responsiveness. Here we describe an experiment which quantitatively examines the role of visual pigment remaining in the albino rat retina which has been exposed to continuous low-intensity light. The ERG sensitivity, rhodopsin content and morphological state of the retina were assessed for various exposure durations. Our findings indicate that reductions in visual pigment levels due to constant light persist indefinitely in the dark. Furthermore, the log ERG (b wave) sensitivity varied directly with the rhodopsin content of exposed retinas even as progressive deterioration was apparent. With respect to this log-linear relationship, light damage resembles 'normal' light adaptation due to short term bleaching exposure.

An especially interesting feature of our results is that even extensive damage could be effected by lights which were considerably dimmer than any previously reported. This lighting was provided by 'cool white' fluorescent bulbs with a sheet of translucent, white plexiglass interposed to give a diffusely-illuminated environment of 50–55 lx measured at right angles to the walls of the enclosures. This light level corresponds to that which is found in many indoor environments. Ambient temperature of the cages was constant at $24 \pm 1^\circ\text{C}$ and the rats moved freely within them.

Constant light exposures ranged from 24 to 108 h and were followed by a period of 12 h in darkness. ERGs were then recorded using a Ag–AgCl cotton wick electrode positioned on the cornea of rats which were anaesthetised

Fig. 1 Light micrographs of transverse sections through albino rat retinas showing different degrees of light damage. *a*, Control retina; *b*, 60-h exposed retina; *c*, 108-h exposed retina. Tissue was fixed in 4% glutaraldehyde and stained with haematoxylin-eosin. Sections were taken from a central region of the retina. IP and G extend beyond the lower edge of the micrograph of the control retina (*a*). $\times 800$.

with sodium pentobarbital. The indifferent electrode was placed on the unstimulated eye and shielded from stray light. Threshold intensity was determined for a criterion b wave of 25–30 μ V using a 20-ms monochromatic flash of 500 nm. Following electrophysiological measurements, the retinas were excised and used for either histological study or rhodopsin assay in which pigment was extracted with 15% Triton X-100.

Control rats were taken directly from an animal room with a 12-h light, 12-h dark cycle of very dim light. After 12-h dark adaptation, their threshold intensities were measured and equated to 1.0 on a relative scale so that log threshold is equal to 0.0. Rhodopsin content of damaged rats is expressed in this study as a percentage of that found in the controls.

Figure 1 shows the degenerative changes of the rat retina resulting from increasing durations of exposure to constant, low intensity light. With 60-h exposure, a shortening and disorganisation of the outer segment layer can be observed (Fig. 1b). Several cell bodies of the outer nuclear layer were missing and compaction of the retina was evident. No obvious changes in the pigment epithelium were revealed by light microscopy. Rats exposed for 108 h were almost completely lacking in identifiable outer segments (Fig. 1c). The outer nuclear layer was reduced to less than one-third

Fig. 2 Time course of sensitivity and rhodopsin content changes with constant exposure to low-intensity illumination. ○, Rhodopsin content; ●, log relative threshold. Standard deviation bars are drawn upon averaged log threshold data points for groups of four animals.

of its original thickness reflecting the loss of many cell bodies; but, of those remaining many seemed to have intact inner segments. In addition, considerably fewer cell nuclei had degenerated in the peripheral retina as compared with the central regions. This distribution of damage has also been observed by previous investigators^{3,4}.

The level of rhodopsin in the retina, as measured after the 12-h dark adaptation period, was continuously lowered with time of exposure to low intensity light. Ordinarily complete regeneration of bleached visual pigment occurs within 2–3 h in the dark⁵. Only 24 h of constant light exposure was sufficient to cause a prolonged reduction in the amount of rhodopsin as compared to the control value. With 108-h exposure, only 11% of the rhodopsin remained. In Fig. 2 it is seen that a steady rise in log b-wave threshold paralleled the depletion of visual pigment. Figure 3 shows the relationship between log threshold and rhodopsin content of the retina for various exposure durations. A linear function between these two variables is obtained which has also been found for retinas bleached (in a conventional manner) with relatively short light exposures^{6,7} and for visual pigment levels reduced by vitamin A deprivation⁸. Thus, our findings demonstrate a third way in which rhodopsin can be varied so that the log ERG threshold depends directly on visual pigment concentration in the retina. It should be noted that the observed rise in threshold due to a reduction in the rhodopsin level is disproportionately higher than what would be expected simply on the basis of the quantal catching ability of the photoreceptors (Fig. 3).

Fig. 3 Relationship between log ERG threshold and reduced visual pigment levels due to constant light exposure. Vertical bars denote the standard deviations of groups of four animals. The dotted line represents the rise in log threshold expected if it were only affected by changes in the probability of quantal absorption by the photoreceptors.

In view of histological changes that are produced by low intensity light exposures, our result implies that even seriously distorted rod outer segments are capable of initiating retinal signals as long as some rhodopsin is present within them. If the cells which generate the b wave can still function at or near their normal capacity following a damaging light exposure, they might only suffer a loss of input in a way that doesn't differ much from 'bleaching' light adaptation. The Müller cells of the inner retina are a likely candidate since they have been implicated as the source cells of the b wave⁹ and have been shown to be spared even after severely damaging light exposures⁴.

Species specific agglutination of eggs by bindin isolated from sea urchin sperm

SPERMATOZOA adhere to eggs during sea urchin fertilisation^{1,2}. The adhesion is between the acrosome process of the sperm and the vitelline layer covering of the egg³. During the sperm acrosome reaction, the membrane of the extending acrosome process becomes coated with protein derived from the sperm acrosome vesicle^{4,5}. We believe^{4,5}, like others⁶, that the acrosome vesicle protein binds the sperm to the egg by interacting with glycoprotein receptors on the egg vitelline layer^{4,5,7,8}. We have isolated the insoluble contents of the acrosome vesicle and have shown it to be composed of a single protein of molecular weight 30,500 which we have named bindin⁴. In most interspecies inseminations sea urchin sperm fail to adhere to the vitelline layers of foreign eggs and fertilisation does not occur, even though sperm undergo the acrosome reaction in the presence of the foreign eggs⁹. Presumably this failure of gamete adhesion occurs because bindin, on the sperm acrosome process, does not bind to the glycoprotein receptors on the vitelline layers of eggs of another species. We report here the species specific agglutination of unfertilised eggs by isolated bindin. This demonstrates the

preservation of the species specific recognition event between the isolated protein and its receptor which should facilitate the *in vitro* reconstruction and analysis of the molecular mechanism of gamete adhesion.

Gametes were spawned into seawater by injecting 0.5 M KCl into adults. Egg jelly layers were dissolved by a 2-min exposure to pH 5 seawater followed by return to pH 8 seawater. Eggs exhibited 100% normal fertilisation as judged by the elevation of the fertilisation envelope within 60 s after a test insemination. Eggs suspensions used in

agglutination tests were stored at 0 °C no longer than 2 h before being discarded. Insoluble, particulate bindin was isolated from sperm as previously described⁴. After the 13,000g centrifugation the pellet of bindin was transferred to siliconised 30 ml correx glass centrifuge tubes and sonicated with the minimum intensity to achieve complete suspension. The bindin was sedimented three times and resuspended by sonication in 15 ml fresh calcium free seawater pH 5.8 (ref. 4). The final pellet was resuspended in normal seawater, the protein concentration was determined¹⁰ and storage was at 0 °C until use. Eggs were placed in wells of an agglutination titre plate, various amounts of bindin suspension added and the plate agitated by either a reciprocal or a rotary motion at 20 °C.

Figure 1 shows that agglutination of eggs by bindin is species specific. The final concentration of bindin in the agglutination mixture (Fig. 1) was $430 \mu\text{g ml}^{-1}$ for *Strongylocentrotus purpuratus* and $230 \mu\text{g ml}^{-1}$ for *S. franciscanus*. By serially diluting the bindin we determined that for both species $3.5 \mu\text{g ml}^{-1}$ was the minimum bindin concentration needed to agglutinate homologous eggs to the extent shown in Fig. 1. In other words, the concentration of bindin used in this experiment far exceeds the minimum needed to achieve maximum agglutination. That the two bindins do not cross react at high concentrations with eggs of the other species suggests the recognition by bindin of its receptor on the egg surface must be unique to each species. Some loss of specificity occurred as the eggs aged, however. *S. purpuratus* eggs older than 2 h post-spawning sometimes show slight agglutination by *S. franciscanus* bindin, but this was never true for the reciprocal cross mixture. If bindin is partially solubilised in 8 mM urea, 2% mercaptoethanol, then dialysed back into seawater, it still agglutinates eggs but the species specificity is lost. The native structure of bindin seems necessary for the species specificity of agglutination. We have reported⁴ that formaldehyde and glutaraldehyde fixed eggs are agglutinated by bindin. The species specificity of agglutination of aldehyde-fixed eggs is not reliably reproducible for reasons we have not investigated.

The older literature on fertilisation¹¹⁻¹³ stressed that the species specificity of fertilisation is based on the existence of specific 'fertilisins' in the jelly layer surrounding the egg. This hypothesis was recently questioned and re-evaluated by Collins¹⁴. We found that the addition of solubilised egg jelly has no effect on the agglutination of eggs by bindin, and that the species specific attachment of sperm to sea urchin eggs is based on the interaction of a sperm protein, bindin, with the egg vitelline layer. Sperm attachment to the zona pellucida covering of the mammalian egg is also a species specific phenomenon^{15,16} which might involve a similar type of recognition between mammalian sperm bindin and zona bindin receptors. Our work with sea urchins is the first demonstration of the species specific interaction of a protein isolated from sperm with the surface of an animal egg.

Expression of α -galactosidase in preimplantation mouse embryos

THE most widely accepted model for X-chromosome dosage compensation in female mammals is the single-active X hypothesis (Lyon hypothesis)¹. X-Chromosome dosage compensation probably occurs at about the time of implantation of the embryo into the uterus^{2,3} but it is not known whether this arises by a process of X-chromosome inactivation or by X-chromosome activation⁴. There is now good evidence for the expression of the embryonic genome during preimplantation development⁵⁻¹⁰ and Lyon^{3,2} has reviewed the evidence suggesting that X chromosomes are also expressed during this period. This includes both indirect observations¹¹⁻¹³ and the more direct experiments with the X-linked enzyme hypoxanthine guanine phosphoribosyl-transferase (HPRT) (ref. 10). We have examined the expression of another X-linked enzyme, α -galactosidase¹⁴⁻¹⁶ and report here a 300-fold increase in activity during preimplantation development. This is probably due to the expression of embryonic X chromosomes.

Large numbers of preimplantation mouse embryos at similar stages of development were obtained by artificial insemination (refs 16, 21). Galactosidase activity was assayed in single embryos using the microfluorometric assay technique described for β -glucuronidase^{17,18}. The α -galactosidase assay mixture contained 2×10^{-3} M 4-methylumbelliferyl- α -D-galactopyranoside (Koch-Light), 0.1 M sodium citrate-citric acid (pH 4.2), 0.9% sodium chloride and 0.1% bovine serum albumin.

Embryos were incubated in microdroplets containing 1-8 nl of reaction mixture at either 37 °C or 25 °C for up to 1 h. To avoid depleting the substrate below the optimum concentration, embryos beyond the eight-cell stage were incubated in the reaction mixture for shorter periods (20 min was the shortest incubation time used). The accuracy of the microassay for α -galactosidase was confirmed using a test-tube fluorometric assay^{19,20} for samples of 20-40 embryos. The embryos were added, in less than 5 μ l of phosphate buffered saline, to a reaction volume of 100 μ l which was then frozen and thawed six times and incubated at 37 °C for up to 6 h. The reaction mixture used was the same as for the microassay and at pH 4.2 the reaction was linear with time for 8 h.

The mean α -galactosidase activity per embryo increased 300-fold (from 10^{-14} to 3×10^{-12} mol product per h per embryo at 37 °C) between the two-cell stage (30 h after artificial insemination) and the blastocyst stage (90 h) for C3H/HeHa embryos (Fig. 1). The rate of increase in α -galactosidase activity per embryo also represents a considerable increase in enzyme activity per cell during the initial cleavage divisions (Table 1). This rapid increase in α -galactosidase activity coincides with the increase in activity of HPRT (ref. 10). Other embryonic genes are also expressed at this time⁸ suggesting that the increased α -galactosidase activity is a result of X-chromosome function during early development.

If both X chromosomes of female embryos are active during early preimplantation development X-chromosome dosage compensation would involve the inactivation of one of two active X chromosomes rather than the activation of

Fig. 1 Increase in mean α -galactosidase activity during preimplantation development of C3H/HeHa mouse embryos. The enzyme activity is expressed as mol of product per h per embryo at 37 °C and results from both microassay (○) and test-tube assay (●) are shown. There is a 300-fold increase in α -galactosidase activity between the 2-cell stage and late blastocyst stage.

one of two inactive chromosomes. It would then be predicted that before X-chromosome inactivation occurs female embryos would have twice the α -galactosidase activity of comparable male embryos, assuming a negligible contribution from the oocyte. The distribution of α -galactosidase activity per embryo for a population of embryos would therefore be expected to be bimodal before X-chromosome inactivation and would become unimodal afterwards.

We have attempted to test this prediction both in order to confirm that both X chromosomes of female embryos are active early in development and to determine whether X-chromosome inactivation occurs before implantation. Bimodal distributions of α -galactosidase activity per embryo were usually obtained for embryos collected at 54 h, and 66 h but in some experiments the distributions were not clearly bimodal. Figure 2 shows the distribution obtained at six time points for our largest experiment in which a possibly bimodal distribution can be seen for the embryos collected at 66 h. Despite our attempts to select embryos at similar stages of development the standard errors for cell counts shown in Table 1 indicate that there is still considerable developmental variation. As the α -galactosidase activity increases very rapidly during this period any

Table 1 Increase in α -galactosidase activity during preimplantation development

Age (h after insemination)	Mean cell no.* ($\pm$ s.e.)	Mean α -galactosidase activity† per cell
30	2	5
42	4	21
54	8	48
66	17.3 ± 0.9	72
78	30.1 ± 2.0	49
90	60.5 ± 4.0	57

*The cell number in 66, 78 and 90 h embryos was determined by the air drying method of Tarkowski²⁰.

†The mean α -galactosidase activity was determined by microassays of 2-cell embryos and test tube assays of older embryos and is expressed as fmol product per cell per h at 37 °C.

Fig. 2 Distribution of α -galactosidase activity per C3H/HeHa mouse embryo at six time intervals after artificial insemination. Individual embryos were assayed at 25 °C using the microassay and in the experiment illustrated the distribution of α -galactosidase activity per embryo is bimodal for 66-h embryos (morulae). The number of embryos in each activity class is indicated by the vertical scale, marked in intervals of five embryos. The mean enzyme activity for each distribution is indicated with an arrow. *a*, 90 h, mean α -galactosidase activity ($\pm$ s.e.) $4,523 \pm 124$ fmol product per h per embryo at 25 °C ($n = 104$); *b*, 78 h, $1,504 \pm 62$ ($n = 91$); *c*, 66 h, $1,094 \pm 38$ ($n = 111$); *d*, 54 h, 386 ± 19 ($n = 99$); *e*, 42 h, 56.1 ± 3.4 ($n = 99$); *f*, 30 h, 8.7 ± 0.3 ($n = 95$).

developmental variation among embryos of the same age would contribute to variation in enzyme activity per embryo and tend to mask any underlying bimodal distribution.

The striking increase in α -galactosidase strongly suggests that X chromosomes are expressed in preimplantation mouse embryos as early as the four cell stage. We have not yet been able to confirm that female embryos have higher levels of α -galactosidase activity than males during preimplantation development. However, the indications of bimodal distributions of α -galactosidase activity per embryo suggest that both X chromosomes are expressed in female preimplantation embryos by the eight-cell to morula stage. These results support the view that X-chromosome dosage compensation occurs by the inactivation of one of two active X chromosomes rather than by the activation of one of two inactive X chromosomes.

Low specific activity of rare allozymes of α -glycerophosphate dehydrogenase in *Drosophila*

ELECTROPHORETIC surveys of *Drosophila* species¹ show that many gene-enzyme systems are essentially monomorphic. Very often, however, one or more populations may contain rare alleles, that is, at frequencies less than 5%. Are these alleles selectively neutral and rare because of historical accidents² or are they deleterious and maintained in populations only through mutation? The dimeric enzyme α -glycerophosphate dehydrogenase (α GPDH) is a good example of an essentially monomorphic *Drosophila* gene-enzyme system. Out of the 101 species of *Drosophila* surveyed thus far for electrophoretic variation of α GPDH (refs 3-5), only *D. melanogaster* is polymorphic. This polymorphism seems to be maintained by selection with temperature being, or strongly correlated with, the selective agent⁶⁻⁸. Microcomplement fixation experiments indicate that this enzyme is evolving slowly among *Drosophila* species and has accepted relatively few changes in its structure⁹. We propose that the rare alleles of the α GPDH locus found in some species (see ref. 5) may be at low frequencies because the products of these alleles (allozymes) are catalytically less efficient than their 'wild-type' counterparts.

To test this hypothesis, the specific activities of all the available rare electrophoretic variants (allozymes) were compared with the specific activities of the common allozymes in six species of *Drosophila*. Two other species, *D. nasuta* and *D. birchii*, for which population survey data are not available were also examined. The 'rare' alleles in these species were those found at low frequencies in laboratory stocks. Although there was an insufficient number of flies homozygous for the rare alleles to determine specific activities for the purified allozymes directly, there is a way to determine them indirectly. α GPDH is a dimeric enzyme and in α GPDH^A/ α GPDH^B heterozygotes the A : A, A : B and B : B dimers can be separated electrophoretically. The activities of each of these allozymes can then be measured densitometrically after staining for α GPDH activity. If it is assumed that each allele produces an equal amount of protein and that the monomers associate randomly, then the relative activities of the A : A and B : B homodimers in the heterozygous flies, in fact, represent the relative specific activities of those two forms of α GPDH (Fig. 1).

The critical assumption that the monomers associate randomly is supported by three facts. First, *in vitro* subunit hybridisation experiments using purified α GPDH from eight species of *Drosophila* have shown that the dissociated monomers of these different α GPDHs reassociate randomly¹⁰. Second, theoretical calculations on the effect of single amino acid substitutions in the subunit contact region of this molecule strongly suggest that they would have little discernible effect on the ratio of dimers in heterozygotes¹⁰. Third, only a minority of the many rare variants of haemoglobin affect the subunit contact regions of this molecule¹¹. Thus, few, if any, of the rare allozymes of α GPDH are expected to be affected in the subunit contact

Fig. 1 Electrophoretic separation of α GPDH allozymes from *D. paramelanica* heterozygous at the α GPDH locus. *a*, Cellulose acetate membrane stained for α GPDH activity after electrophoresis. Electrophoresis was carried out in a Beckman Microzone Cell at 300 V for 1 h, in a buffer consisting of one part Tris-barbital-sodium barbital buffer (0.025 ionic strength, pH 8.8) and one part Tris-HCl buffer (0.1 M, pH 8.3). The membranes were stained for 10 min at 20 °C in 25 ml of 0.05 M Tris-HCl buffer, pH 8.3, which contained 15 mg NAD⁺, 5 mg MTT tetrazolium, 3 mg phenazine methosulphate, 200 mg α -glycerophosphate, and 375 mg agar. For the staining time used, the deposition of dye is linear and therefore proportional to enzyme activity (G.E.C., unpublished results). *b*, Densitometer scan of the stained membrane. The area under the B:B peak compared with that under the A:A peak is taken as the relative specific activity of the B:B homodimers.

region of this molecule. It is also doubtful that such effects would alter the ratio of dimers in heterozygotes.

Table 1 lists the observed activity ratios for α GPDH in heterozygotes, together with those expected on the basis of the relative specific activities calculated as outlined. Although there are no gross departures from expectation in these values, there are consistent deficiencies for the

observed values for the heterodimers. The most likely explanation is that the heterodimers do not have specific activities exactly intermediate to those of the respective homodimers, as assumed for calculating the expected ratios in Table 1, but rather have specific activities slightly lower. Thus, in spite of the approximate nature of the calculation, we feel that this is a valid means of estimating the relative specific activities of rare allozymes of α GPDH.

The activities of nine rare allozymes (the B:B allozymes) thus calculated (Table 1) are all lower than their wild-type counterparts (the A:A allozymes). In addition, although the electrophoretic separation of the dimers in α GPDH^A/ α GPDH^B heterozygotes of *D. immigrans* was not sufficient to make a densitometric tracing, it could be seen that the B:B homodimer was not as intensely stained as the A:A homodimer. From these results it might seem that α GPDH^B of *D. birchii* might be a rare allele in natural populations and that α GPDH^B in *D. nasuta* might be polymorphic. Surveys of α GPDH variation in populations of these two species would represent a further test of this hypothesis.

It is also interesting that homozygotes for the rare alleles in some species have low viabilities, reduced fertility and/or longer developmental times. For example, in *D. putrida*, α GPDH^B/ α GPDH^B homozygotes were obtained from matings between heterozygotes, but no adult flies ever eclosed from crosses between these α GPDH^B homozygotes. In *D. tripunctata*, homozygotes for the rare allele were viable but their egg-adult developmental period was 3–4 d longer than wild-type flies raised in the same conditions. The same was true in *D. algonquin*, except that the developmental time of the α GPDH^B homozygotes was only increased 2–3 d. Although the possibility that these effects are due to other closely linked deleterious genes cannot be completely ruled out, it is unlikely that this is the case because none of the α GPDH^A/ α GPDH^A stocks established from single pair matings ever exhibited these characteristics.

The total activity of α GPDH measured on cellulose acetate membranes is virtually the same for α GPDH^A/ α GPDH^A and α GPDH^B/ α GPDH^B homozygotes, although the two homodimers in a heterozygote do not have the same relative activities. This is true even in those species

Table 1 Ratio of α GPDH dimers in heterozygotes and relative specific activities of α GPDH produced by rare alleles

*The common allele in each species is designated A. Except for ¶, the remaining alleles occurred in natural populations at frequencies < 0.02 (refs 6,7).

¶The alleles for these species were found in laboratory stocks. Their frequency in wild populations is not known.

‡The expected ratio was calculated using the relative specific activities of the A:A homodimer as $p = 1$, and that of B:B as $q < 1$, (see †). Then the expected ratio is $A:A = p/2(p+q)$; $A:B = (p+q)/2(p+q)$; and $B:B = q/2(p+q)$.

†The method for determining relative specific activities is discussed in the text and Fig. 1. Each recorded value is an average of 4–8 separate determinations.

having a rare allozyme of rather low relative specific activity, for example *D. putrida*. Berger¹² pointed out that the activity level of an enzyme may be an important factor in the maintenance of protein polymorphism. Thus, an individual which has to make more of a less active allozyme may suffer from the biochemical cost of increased synthesis. In this regard, α GPDH is surely a major protein component of the adult fly, for it is homogeneous after only some 500-fold purification of crude extracts of *D. melanogaster*¹³.

Although additional biochemical characterisation of these allelic products is needed, the preliminary results indicate that the enzymes made by the rare alleles at the α GPDH locus are molecules with lowered enzymatic efficiency (although tightly linked *cis* regulatory sites can be associated with different XDH allozymes in *D. melanogaster*)¹⁴. It therefore seems reasonable that these alleles are rare because they are selected against in natural populations. Whether this holds for rare alleles in other *Drosophila* gene-enzyme systems remains to be determined.

Phenotypic characterisation of a unique non-T, non-B acute lymphoblastic leukaemia cell line

MANY human lymphoblastoid cell lines have been established from subjects with different haemopoietic disorders as well as from normal individuals¹⁻³. In most cases the inability to identify the precise origin of cells which have been established has limited the usefulness of these lines, especially those derived from leukaemic donors. Although there are a few important exceptions to this generalisation (2, 3, 4 and see below) it is significant that no lines have been established from the common form of acute lymphoblastic leukaemia (ALL) which is usually referred to as 'null' cell or 'non-T, non-B' ALL (refs 5-7). We describe here the establishment of a lymphoid cell line, Reh, derived from an acute lymphocytic leukaemia where the leukaemic identity of established cells is supported by kinetic data, chromosome markers and detection of leukaemia associated antigens and enzymes.

Reh cells do not contain detectable Epstein-Barr virus (EBV), either by the nuclear antigen (EBNA) test or by nucleic acid hybridisation (to be published elsewhere). This line was initiated from the peripheral blood of a 15-yr-old girl in relapse with 100% lymphoblasts in her bone marrow and 146,000 white blood cells (mm³) with more than 95% lymphoblasts in her peripheral blood. Clinical and haematological features including morphology and histochemistry of the leukaemic blasts were characteristic of ALL.

Details of culture and karyotype techniques have been described previously⁸. Karyotypes were obtained and studied at the time of seeding the culture, and after establishment without addition of PHA. Fresh leukocytes consisted of populations which were cytogenetically different, one normal: 46, XX, the other abnormal: 45, XX, -2B, +1C (Fig. 1a).

Denaturation techniques have suggested that the two missing B are possibly one number 4 and one number 5 and further indicated that the extra C is not a true C, but probably reflects a structural rearrangement. Early in the course of establishment, chromosome examination revealed that the selection of the abnormal population had

Fig. 1 Chromosome preparations from Reh cells. To, Fresh cells. Ti, Established line. See text for interpretation.

occurred since all the cells showed the 45, XX, -2B, +1C karyotype (Fig. 1b). Disappearance of the normal population was confirmed by further sequential examinations. Analysis with banding techniques is necessary to establish the precise nature of Reh chromosomal characteristics. The results so far, however, indicate clearly that the cells established *in vitro* belong to the same cytogenetically abnormal clone as the patients' uncultured leukaemic cells.

In contrast to the situation found with normal B-cell lines, the Reh cells started to divide at the beginning of the culture. This can be seen in Table 1 from the percentage of mitosis and from the cell uptake of tritiated thymidine (³HTdr). These observations suggest that abnormal leukocytes were immediately able to proliferate in the culture medium and overcome the cytogenetically normal population.

The fresh Reh cells and the Reh line when established were examined for reactivity with a small panel of membrane markers. The initial cells from the patient and the

Table 1 Tritiated thymidine uptake and percentage of mitosis during the establishment of the Reh cell line.

Time in culture (d)	% ³ HTdR labelled cells	% Mitosis
0	14.1	0.13
7	11.4	0.12
14	10.6	0.23
26	9.4	0.17
42	12.1	0.32
54	20.9	0.28
67	13.2	0.45
77	17.5	0.85
96	19.2	0.90
201	22.9	1.10

The percentage of DNA synthesis was determined by the 'dipping' autoradiographic technique. After incubation for 1 h at 37 °C with ³HTdR (1 µCi ml⁻¹ TMM 79 B, CEA, France) the cells in suspension were centrifuged (5 min at 800 r.p.m.), spread and fixed 10 min in methanol. The slides were dipped in Ilford K2 emulsion at 45 °C, dried and set in the dark at 4 °C. Exposure time was 7 d. After development (Kodak D19B, AL4) the slides were rinsed under water, dehydrated for 45 min with ethanol 70 °C and coloured with Giemsa dye. The labelling index was determined by counting 1,000 cells. The percentage of mitosis was measured on 10,000 Giemsa-stained cells before establishment and on 2,000 cells after establishment.

established cell *in vitro* were negative for sheep erythrocyte rosette formation and surface immunoglobulin and could therefore be considered to be of the common type of ALL (that is 'null' ALL or 'non-T, non-B' ALL). Soon after establishment a small proportion of the Reh cells seemed to have cell surface C3 binding sites as determined by the EAC rosette assay²; however these were no longer detectable after a few months of culture.

The Reh line has now been maintained in culture for 2 yr and during this time has been used for active immunotherapy. Recently several new leukaemic cell markers have become available^{6,10,11} and so a more extensive phenotyping

of the Reh line has now been carried out. Table 2 shows the results of this analysis in which the phenotype of Reh is compared with that observed in a large series (400) of ALL cases^{6,12}. The phenotype profile of Reh is indeed essentially identical to that of the common form of ALL. The crucial markers here are the anti-ALL sera¹³, anti-p28,33 serum^{12,14} and the enzymes hexosaminidase (intermediate peak isoenzyme)¹² and terminal deoxynucleotidyl transferase¹⁵ since these together constitute a phenotype unique to non-T, non-B ALL¹². Figure 2 illustrates the reactivity of Reh cells with anti-ALL. Absorption of anti-ALL serum with Reh cells removes all binding activity against fresh ALL cells (M.G., unpublished) indicating complete cross-reactivity of the ALL antigen on Reh and non-T, non-B ALL.

Several cell lines have been established from ALL by other investigators. With rare exceptions, however, these have either been EBV positive B cells (presumably derived from the patient's normal B cells) or in cases of Thy or T-like ALL, they have been EBV negative T-cell lines^{16,17}. The latter are presumably leukaemic cell derivatives and in some cases this has been confirmed by chromosome markers. An exception to this generalisation is the establishment of the line NALM-1 from a child with Philadelphia positive CML in blast crisis⁴. The membrane phenotype of this line is the same (with respect to those markers tested) as Reh including the expression of the ALL antigen⁴. This observation accords with recent studies indicating that some cases of CML and non-T, non-B ALL may originate from a common target cell¹⁸. In general it has proved impossible to establish non-T, non-B ALL cell lines (J. Minowada, personal communication). The only reported exceptions in addition to Reh and the Ph¹ positive NALM-1 are two lines of non-T, non-B ALL established from the cells of patients in relapse¹⁹. It may be that the only non-T, non-B ALL type cells which have a capacity

Horizontal axis: relative cell size. *a*, Reh cells stained with rabbit anti-ALL followed by fluorescein labelled goat anti-rabbit Ig. *b*, Reh cells treated with normal rabbit serum followed by fluorescein labelled goat anti-rabbit Ig. See ref. 6 for details of FACS and fluorescence staining methodology.

for unlimited growth *in vitro* are those which are aneuploid with major chromosomal alterations. These changes may occur at the onset of the disease and affect all members of the leukaemic clone or more frequently may arise after treatment in a subclone (perhaps in Ph negative ALL). The ability of these exceptional ALL or CML blast crisis cells to grow *in vitro* may be a correlate of their growth patterns *in vivo* since relapsed ALL is often more drug resistant than previously untreated ALL (ref. 20) and Ph⁺ positive disease, even when presenting with an ALL phenotype, has a worse prognosis than Ph⁻ negative ALL in the same age group^{18, 21, 22}.

The availability of cell lines which are clearly derived from the common form of lymphoblastic leukaemia may be of considerable value in further investigations on the nature of leukaemia-associated antigens, and the block to further differentiation which presumably exists in these cells. The Reh line has been used extensively for active immunotherapy of ALL patients in Villejuif²³. It is possible that the therapeutic efficacy of Reh might be different from that of fresh allogeneic ALL cells. The ALL associated antigen might in combination with allogeneic histocompatibility antigens provide a suitable target for the patients' immune system. We are currently testing sera from treated patients to see if antibodies are present against the ALL antigen which the rabbit antisera recognise.

Human B cell, T cell and null cell leukaemic cell lines derived from acute lymphoblastic leukaemias

CONTINUOUS culture of human leukaemic cells is still a difficult task, although several leukaemic cell lines have been derived from patients with acute and chronic myelogenous leukaemia^{1,2} and acute lymphoblastic leukaemia (ALL) (refs 3–6). We describe here B-cell, T-cell and null-cell leukaemic cell lines newly established from three patients with ALL.

Leukaemic cells separated by dextran sedimentation from peripheral blood or bone marrow were resuspended in growth medium at a concentration of 1×10^7 cells per ml and dispersed into 35-mm Petri dishes (2.5 ml per dish). The cultures were incubated at 37 °C in a humidified atmosphere of 7.5% CO₂ in air. Two kinds of growth media were used: medium I consisted of RPMI 1640 supplemented with 20% human cord serum (HCS) and medium II of RPMI 1640 supplemented with 20% foetal calf serum (FCS). Partial medium changes were done twice a week. After cell line establishment, subcultures were made usually once a week.

Cells were examined for receptors for sheep erythrocytes (E), Fc fragment of IgG (EA) and complement (EAC). They were also tested for surface immunoglobulin (Ig) by direct immunofluorescence with FITC-conjugated goat antisera (Behringwerke) monospecific for human IgM, IgG, IgA and light chains. All these assays were performed as described by Jondal and Klein⁷. Epstein-Barr virus (EBV)-determined nuclear antigens (EBNA) was tested for by anti-complement immunofluorescence⁸. Karyotypes were analysed as described previously⁹.

A B-cell line (BALL-1) was derived from peripheral blood of a 75-yr-old man who died 1.5 months after the onset of ALL. Culture was initiated on 15 January 1976

and established only in medium I 1 month later. The peripheral leukocyte count at the beginning of culture was 25×10^4 per cm^3 with 83% lymphoblasts. Both peripheral lymphoblasts and BALL-1 cells were virtually 100% surface Ig-positive for two heavy chain classes IgM and IgA. The light chain was of the lambda type. Cells from both sources contained 36–60% EA and EAC rosetting cells but neither of them formed E rosettes. Autopsy on this patient revealed no lymphadenopathy or tumorous masses.

A T-cell line (TALL-1) was established from bone marrow of a 28-yr-old man who developed the terminal leukaemic phase of lymphosarcoma. Marrow cells cultured on 13 April 1976 grew equally well in both medium I and II after 1 month. The marrow at the time of culture contained 94% lymphoblasts. The majority of marrow lymphoblasts and TALL-1 cells formed E rosettes but neither of them bore surface Ig.

A null-cell line (NALL-1) was obtained from peripheral blood of a 14-yr-old boy who relapsed after a 3-month remission. Culture was started on 16 March 1976 and established only in medium I 2 weeks later. At the time of culture initiation, the peripheral leukocyte count was 18.8×10^4 per cm^3 with 98% lymphoblasts. Neither peripheral lymphoblasts nor NALL-1 cells demonstrated E rosette formation or surface Ig. Receptors for EAC but not for EA were detected on a small percentage (less than 8.1%) of NALL-1 cells, however.

Cells from BALL-1, TALL-1 and NALL-1 grew in single cell suspension with a doubling time of 60–90 h and were morphologically identical to the original lymphoblasts of the respective donor. These cell lines were all repeatedly negative for EBNA when tested by us and in the laboratory of Dr Yoriko Hinuma, and hence considered EBV genome-free.

Karyotypic analysis was performed on these cell lines between 7 and 9 months after culture initiation. Fifty metaphases were studied from each sample and several selected metaphases were further analysed by the Giemsa banding technique. BALL-1 had a pseudodiploid mode with four characteristic markers (one each of large telocentric and metacentric chromosomes and two medium-sized telocentric chromosomes). Two metaphases were obtained from peripheral lymphoblasts from the BALL-1 donor, both of which were pseudodiploid. The chromosomes of the TALL-1 line were all in the hypertetraploid region, ranging from 95 to 101. No chromosome preparations were made directly from the donor of the TALL-1 line. NALL-1 had a hypodiploid mode of 43 with a minute marker and missing sex chromosomes. Peripheral lymphoblasts from the NALL-1 donor yielded three analysable metaphases, which all showed 43 chromosomes and the minute marker observed in the NALL-1 line.

When BALL-1, TALL-1 and NALL-1 were stained with rabbit anti-human thymocyte serum by indirect membrane immunofluorescence, only TALL-1 cells were fluorescent, indicating the absence of thymus-related antigen on BALL-1 and NALL-1 cells. The anti-thymocyte serum had been extensively absorbed with 'normal' lymphoblastoid cell lines, chronic lymphocytic leukaemia cells and normal peripheral leukocytes, and known to react specifically with MOLT-4 (leukaemic T-cell line) and thymocytes. Furthermore, BALL-1 and NALL-1 were found to stimulate allogeneic lymphocytes in one-way mixed lymphocyte reactions whereas TALL-1 was non-stimulatory.

Continuous multiplication of B-cell and null-cell leukaemic cells in medium I in contrast to their rapid degeneration in medium II suggests that HCS is more growth-supporting than FCS for certain human ALL cells. On the other hand, T-cell lymphoblasts grew equally well in both medium I and II; this is consistent with the establishment of T-cell ALL lines in other laboratories in

medium containing FCS (refs 3–6). Both BALL-1 and NALL-1 initially established in medium I were then adapted to grow in medium II, although they tended to multiply better in medium I than in medium II. Another advantageous point of the supplemental use of HCS is that antibody present in HCS against EBV capsid antigen (VCA) would suppress transformation of coexisting normal B lymphocytes by EBV (ref. 10). The pooled HCS that we used in the present experiment had an anti-VCA titre of 1:160.

The assumption that all of BALL-1, TALL-1 and NALL-1 originated from leukaemic cells is based on the findings that they uniformly lack the EBV genome, have morphology and surface characteristics identical to those of the leukaemic cells of the corresponding donor and have various chromosome abnormalities including those found in the pre-culture lymphoblasts. Therefore, these cell lines are distinct from EBV-carrying lymphoblastoid cell lines of normal B-lymphocyte origin¹¹.

A question may still be raised as to the possible derivation of the BALL-1 line from normal B lymphocytes of the leukaemic patient, even though it is EBV-negative. This would be unlikely, however: rare cases of B-cell ALL do exist^{12,13}; EBV-negative lymphoblastoid cell lines have never been established from normal tissues¹¹; and in addition to the characteristics described above; BALL-1 cells have produced serially transplantable lethal tumours in newborn hamsters treated with anti-lymphocyte serum (unpublished data).

Minowada *et al.*¹⁴ have established a Ph¹ chromosome-positive non-T non-B (null-cell) line from a child with chronic myelogenous leukaemia in blast crisis. Clearly, this cell line is different from NALL-1 with respect to the Ph¹ chromosome and its derivation. The B-cell and null-cell leukaemic cell lines we describe here are unique and, used together with T-cell lines, should contribute to further understanding of human lymphocyte subpopulations in normal and leukaemic states.

This work was supported by the Ministry of Health and Welfare and the Ministry of Education of Japan. We thank Drs Takeshi Sairenji and Yoriko Hinuma for performing the EBNA test.

In vitro immunisation against human tumour cells with bacterial extracts

LYMPHOCYTES from normal persons can become immunised to a variety of tumour cells by exposure to tumour cells *in vitro*¹⁻³. Since close antigenic relationships between micro-organisms and some tumour cells have been demonstrated⁶⁻⁹, studies were carried out to see if bacterial antigens could similarly immunise lymphocytes from normal persons *in vitro* against some tumour cells. The experiments reported here indicate that not only is this possible, but that the cytotoxicity of bacterial immunised lymphocytes is sometimes greater than when lymphocytes are sensitised by intact tumour cells.

Soluble bacterial extracts were prepared from the Glaxo strain of *Mycobacterium bovis* (BCG), *Listeria monocytogenes* (LM), *Escherichia coli* (EC), and *Staphylococcus aureus* (SA), as previously described¹⁰ and are referred to as BCG-SS, LM-SS, EC-SS, and SA-SS, respectively. Their nitrogen (N) concentrations were determined¹¹ and they were passed through a Millipore filter before use.

Breast tumour cells that originated from the pleural effusion of a patient with breast carcinoma were obtained from Dr G. Seman, MD Anderson Hospital, Houston, Texas¹². Malignant melanoma cells (RPMI-7932 and RPMI-8322) were provided by Dr G. E. Moore, Denver General Hospital, and are referred to as melanoma-1 and melanoma-2. Melanoma-1 originated from a pleural effusion and melanoma-2 was established from a metastatic solid tumour lesion. Tumour cells were maintained in tissue culture¹.

Peripheral blood lymphocytes were obtained from 12 normal tumour-free persons. Lymphocytes were then isolated and purified over Ficoll-Hypaque⁴. The purified lymphocytes contained less than 5% polymorphonuclear leukocytes and 5-10% monocytes. These were sensitised with mitomycin C treated tumour cells as previously described⁴ or with various concentrations of the bacterial extracts. The cytotoxicity of *in vitro* sensitised cells was then measured by a ⁵¹Cr release assay¹⁻⁴. Results were compared with the capacity of the same cells to kill normal lymphoblastic target cells. In only one case (donor number 4) was there as much as 25% specific ⁵¹Cr release from normal lymphoblasts (Table 1). Accordingly, ⁵¹Cr release of 25% or more was chosen in this report as the criterion for specific cytotoxicity.

BCG-sensitised lymphocytes from eleven donors caused a greater release of ⁵¹Cr (28% to 78%) from melanoma-1 cells than from the control lymphoblasts (-2% to 21%). Melanoma-2 cells were killed by BCG-immunised lymphocytes from two of three donors and breast tumour cells were killed by BCG-immunised lymphocytes from five of eleven donors. LM-sensitised cells from all seven donors were similarly cytotoxic to melanoma-1 cells and LM-sensitised cells from five of seven donors were cytotoxic to breast tumour cells. In contrast, lymphocytes from only three of seven donors treated with SA-SS became cytotoxic to melanoma-1, and two of seven became cytotoxic to breast tumour cells. Lymphocytes from four donors were treated with EC-SS and none of these developed appreciable cytotoxicity against either melanoma or breast tumour cells. Generally, LM-SS appeared on a nitrogen basis to be more immunogenic than BCG-SS. In some cases, as little as 2 µg N of LM-SS effectively immunised normal lymphocytes. Data from individual experiments where lymphocytes from normal donors were treated with equivalent amounts of BCG, LM, and EC are presented in Fig. 1.

Lymphocytes from some of the donors that were pre-treated with phytohaemagglutinin (PHA), pokeweed mito-

gen (PWM), and concanavalin A (con A) were also treated as effector cells. PHA treated lymphocytes from four of ten persons became cytotoxic to melanoma-1 cells and cells from three of five donors that were PWM treated became cytotoxic to melanoma-1 and one of these also to breast tumour cells. Lymphocytes from one of six donors treated with con A became cytotoxic to melanoma-1 and none to breast tumour cells. PHA treated lymphocytes have

Fig. 1 *In vitro* immunisation of lymphocytes against human tumour cells with bacterial extracts. Lymphocytes were sensitised with different concentrations of: a, BCG extract (BCG-SS); b, *Listeria monocytogenes* extract (LM-SS); c, *Escherichia coli* (EC-SS). Sensitised lymphocytes were tested against target cells: Δ, melanoma-1 tumour cells; ▲, melanoma-2 tumour cells; □, breast tumour cells; ○, normal lymphoblasts. % Specific lysis of ⁵¹Cr-tumour cells was measured. Only standard deviations greater than 1% are indicated.

previously been shown to be cytotoxic to some tumour cells¹³⁻¹⁶. The degree of cytotoxicity observed in this study was relatively less and more variable with the mitogens tested than those produced by the bacterial extracts, however, especially against breast tumour cells. This would tend to minimise the possibility that the cytotoxicity initiated by the bacterial extracts was entirely due to mitogenic effects.

If *in vitro* sensitisation of lymphocytes by bacterial

Fig. 2 *In vitro* immunisation of lymphocytes with tumour cells or bacterial extracts. a, Lymphocytes were sensitised with breast tumour cells (Δ), BCG-SS (□), or LM-SS (○) and tested against breast tumour cells. Number of immunising tumour cells shown in parenthesis. b, Lymphocytes sensitised with melanoma-1 cells (Δ), BCG-SS (□), or LM-SS (○) and tested against melanoma-1 cells (Δ). Number of immunising tumour cells in parenthesis. When anti-BCG coated melanoma cells and anti-*Listeria* coated melanoma cells were the target cells, results are indicated by broken lines. % Specific lysis of ⁵¹Cr-tumour cells measured in each case.

extracts is related to antigenic similarities, it is conceivable that three tumour cell lines tested may also have common antigenic determinants. This possibility has been tested and the results suggest this is the case (manuscript submitted for publication).

The possibility exists that the cytotoxic reactions observed between the effector and target cells were due to histocompatibility differences. When lymphocytes were tested

as target cells, however, there was considerably less cytotoxicity and sometimes no specific ^{51}Cr release. Lymphocytes from three donors and the breast tumour cells were kindly typed for HL-A antigens by Dr Robert McCalmont, Veterans Hospital, Denver, Colorado. Melanoma-1 was previously typed in Dr Paul I. Terasaki's laboratory, University of California, Los Angeles. No HL-A antigens were found on breast cells and only HL-A 2 was found

Lymphocytes were sensitised in 0.75 ml of minimal essential medium containing 20% heat inactivated human AB plasma. Fewer than 1% monocytes were present in sensitised cell population. Cytotoxic activity of sensitised cells was tested against breast, melanoma-1 (mel-1), melanoma-2 (mel-2), and normal lymphoblast cells in ^{51}Cr release assay in triplicate. Normal target cells were normal lymphocytes that have been transformed by PHA or PWM.

*The range of bacterial concentrations used was 18 μg to 36 μg N.

†The adjusted percentage of specific ^{51}Cr release was calculated as:

$$\frac{\text{test release} - \text{minimum release}}{\text{maximum release} - \text{minimum release}} \times 100$$

Controls (minimum values) for each experiment included incubation of target cells alone or target cells with normal unsensitised lymphocytes. Control values were 8–16% for breast, 12–22% for melanoma-1, 18–20% for melanoma-2, and 10–16% for PHA-treated normal lymphoblasts. There was no significant difference between background calculated from target cells incubated alone or target cells incubated with lymphocytes which were cultured alone for 5 d. Maximum values (freeze-thaw $\times 4$) varied between 70 to 83% (average 77%) for melanoma-1, 66 to 72% for melanoma-2, and 68 to 82% (average 72%) for breast tumour cells.

‡A and A $_1$ are two different bleedings from donor 1.

Lymphocytes were sensitised with PHA, PWM, or con A for 5 d and cytotoxic activity was tested against breast, melanoma-1, melanoma-2, and normal lymphoblast cells.

*1:4 dilution of concentration recommended by Wellcome Reagent Ltd. of PHA or PWM was used to stimulate lymphocytes. Con A was used at 1 $\mu\text{g } \mu\text{l}^{-1}$.

†A and A₁ are two different bleedings from donor 1.

on the melanoma-1 cells. Lymphocytes from two of three donors who had HL-A2 were still immunised to melanoma-1 with bacterial extracts. This would suggest that the cytotoxicity observed was not directed towards the histocompatibility antigens of the target cells. The possibility that histocompatibility was not a factor in the phenomenon described will need to be confirmed in a syngeneic system in experimental animals.

In some experiments, cytotoxicity of bacterial immunised lymphocytes was greater than when lymphocytes were sensitised by tumour cells (Fig. 2). In addition, in a series of experiments, ^{51}Cr melanoma-1 cells were incubated with rabbit antisera to BCG or LM for 30 min at 37 °C, washed twice, and then used as target cells. This further augmented the cytotoxicity of bacterial extract immunised lymphocytes (Fig. 2b). Normal sera from the same rabbits that had been obtained before immunisation did not augment cytotoxicity.

Our results indicate that some bacterial antigens can, in *in vitro* conditions, render lymphocytes from normal persons cytotoxic for some tumour cells. The observation that killing of tumour cells by immune lymphocytes was augmented if the tumour targets were coated with antibodies specific for the bacterial extract used suggests in addition that the antibody dependent cellular cytotoxicity (ADCC) mechanism may be involved. ADCC has been shown to be operative against a variety of tumour cells *in vitro*.

The bacterial extracts used in this study are known to consist of many components, only a few of which may be critical for the effects described above. Further studies are needed to isolate and characterise the antigenic portions of bacterial extracts that transform lymphocytes from normal persons into lymphocytes with strong antitumour

activity. It is of interest in this regard that antigenic similarities between melanoma cells and BCG have been demonstrated¹⁷. It is thus tempting to speculate that *in vivo* immunisation with bacteria which crossreacts with tumours may induce cytotoxic lymphocytes to certain tumour cells.

We thank Drs G. E. Moore and G. Seman for providing human tumour lines, and Anita Roybal, Kim Austin, Susan Beeler, Cynthia Bradley, and Pat Stem for technical assistance. This work was supported by the US NCI.

Cyclic nucleotide fluctuations during steroid induced meiotic maturation of frog oocytes

MATURING oocytes of the frog *Rana pipiens* arrest in prophase of the first meiotic division, when they can be isolated and induced to complete meiotic maturation *in vitro* by exposure to steroid hormone. A study of the meiotic maturation divisions of the frog oocyte therefore encompasses problems of steroid action and the control of cell division. An unusual feature of the interaction of steroids with the oocyte is the independence of the nucleus indicated by the failure of actinomycin D or enucleation to affect the induction of maturation by steroids¹. Furthermore, the interaction is nonspecific, in that several different steroids are capable of inducing maturation *in vitro*². Both cyclic AMP and theophylline inhibit progesterone induced maturation³. This report presents evidence that exposure of prophase-arrested oocytes to progesterone lowers intracellular cyclic AMP and cyclic GMP levels, that theophylline inhibits one component of this response, and that periodic cyclic nucleotide fluctuations occur during the subsequent maturation divisions.

The *R. pipiens* oocyte is particularly useful in an investigation of this nature. *In vitro* maturation of a group of isolated oocytes is intrinsically synchronous, and the appearance of characteristic morphological markers allows their progression through the meiotic divisions to be followed under the dissecting microscope. Furthermore, their extraordinarily large diameter—1,500 μm —allows microinjection of substances to active concentrations without markedly changing intracellular volume.

Gravid *R. pipiens* females obtained from December through April were maintained in artificial hibernation at 4 °C until sacrifice. Oocytes were manually dissected from their ovarian follicles with watchmaker's forceps, and exposed to progesterone at 5 mg l⁻¹ for 10 min. Incubations were carried out in amphibian Ringer's solution (100 mM NaCl, 1.9 mM KCl, 1.1 mM CaCl₂, 1.2 mM NaHCO₃, pH 7.8) at 22 °C. In control groups of 50–100 oocytes, at least 95% underwent proper development as determined by activation of the mature oocyte.

The cyclic nucleotide content of isolated *R. pipiens* oocytes which had not been exposed to progesterone (hereafter referred to as basal level) was 0.6 pmol cyclic AMP (range 0.3–1.1) and 8.0 pmol cyclic GMP (range 5.2–14.9) per oocyte, or approximately 0.6 μmol cyclic AMP and 8.0 μmol cyclic GMP per litre cell water (mean from ten experiments). The mean ratio of basal cyclic GMP content to cyclic AMP content was 15 (range 9–29), in marked contrast to the situation found in the oocytes of other amphibians⁴, and in other cell types (for example ref. 5). Basal levels found in samples of oocytes from the same female showed acceptable variation with standard errors which were 4–5% of the mean (three females, three samples per female, data not shown).

Time courses for fluctuations in the levels of cyclic AMP and cyclic GMP during the progesterone-induced *in vitro* maturation of isolated oocytes are presented in Fig. 1. The data show that significant decreases in the levels of both cyclic AMP and cyclic GMP occur within 30 min after exposure to progesterone. The decreases were not observed in experiments in which the control oocytes did not mature.

An antagonistic interaction between intracellular levels of cyclic AMP and cyclic GMP was formulated by Goldberg in terms of a yin-yang relationship¹¹, and McMahon has applied this concept to the regulation of cell division¹². Curiously, from the time of induction until germinal vesicle breakdown (GVBD), or dissolution of the prophase nucleus, the patterns of cyclic AMP and cyclic GMP

fluctuation are similar, yet after GVBD this trend is reversed and a reciprocal relationship is observed. According to Berridge¹³, these patterns of cyclic nucleotide fluctuations reflect monodirectional and bidirectional

Fig. 1 Cyclic AMP (a) and cyclic GMP (b) levels during progesterone-induced maturation of isolated oocytes expressed as % of basal $\pm$ s.e.m. Abscissa shows time elapsed between exposure to progesterone and sampling. Zero on the time scale refers to basal cyclic nucleotide levels. At the times indicated, either a single sample of 30 oocytes, or duplicate samples of five oocytes were selected under the microscope on the basis of morphology when possible and analysed for cyclic nucleotide content. Cyclic nucleotides were extracted by rapidly homogenising samples of oocytes plus medium in two volumes of absolute ethanol at 0 °C. Immediately following homogenisation 3.8 nCi of ³H-cyclic AMP (38 Ci mol⁻¹) and 2.1 nCi of ³H-cyclic GMP (3.5 Ci mol⁻¹) were added to the homogenate in order to follow recovery from the purification steps. The tritiated cyclic nucleotides amounted to less than 5% and 4% of the total amount of cyclic AMP and cyclic GMP, respectively, in the sample. The homogenate was then centrifuged at 6,000 g for 10 min at 4 °C. The supernatant was flash evaporated under reduced pressure and frozen. Purification and separation of cyclic AMP and cyclic GMP was accomplished by sequential column chromatography over neutral alumina and Dowex 1 $\times$ 8 (formate form) according to Jakobs *et al.*⁶ and Butcher *et al.*⁷, respectively. Cyclic AMP and cyclic GMP were measured by the radioimmunoassay procedure of Steiner *et al.*⁸ as modified by Harper and Brooker⁹. Cyclic AMP was also measured by the protein binding assay of Brown *et al.*¹⁰ Both assay procedures for cyclic AMP gave the same results. Authenticity of cyclic nucleotides was established by incubating aliquots of purified extract with 10 μg of beef heart phosphodiesterase, after which less than 5% of the binding activity in the assays remained. Data from several experiments were pooled by first normalising the data within each experiment, expressing every point as % of basal level in oocytes from that particular female. Values from samples collected less than 90 min apart in different experiments were used to calculate a mean value of several experiments for cyclic nucleotide content at a given time point. All points are mean values $\pm$ s.e.m. from three or more experiments. Student's *t*-test was used to establish by paired comparisons whether there was a statistically significant difference between the mean at a given time point and the basal level (100%). Cyclic GMP was significantly different from basal at only one time point after GVBD. Stars indicate a statistically significant difference from basal ($P < 0.05$ – $P < 0.001$). NB, nuclear breakdown (GVBD); M1, first metaphase; PB, extrusion of first polar body; M2, arrest at second metaphase.

control, respectively. The apparent switchover from monodirectional to bidirectional control suggests that an alteration of cyclic nucleotide metabolism occurs at GVBD.

Berridge proposes that an antagonistic relationship exists between cyclic AMP and Ca^{2+} , with cyclic GMP levels simply reflecting intracellular Ca^{2+} levels. A number of studies have suggested that Ca^{2+} has an important role in the induction of maturation. It has been reported that alterations of calcium flux accompany progesterone induced maturation¹⁴, and that the divalent cation ionophore A23187 (ref. 15), as well as propanolol¹⁶, and lanthanum ions¹⁷ can induce maturation of *X. laevis* oocytes. Ionophore A23187 can induce maturation of *R. pipiens* oocytes (A. B. Kostellow, G. A. Morrill, personal communication), as well as parthogenetically activate ova¹⁸.

Cleavage of the sea urchin egg is accompanied by a cycle of cyclic AMP fluctuations¹⁹ similar to those shown in Fig. 1, and similar fluctuations of cyclic AMP occur during proliferation of mammalian cells in culture²⁰. The significance of these fluctuations has not been established, however.

To investigate the physiological significance of decreased cyclic nucleotide levels in the mechanism of induction of maturation by progesterone, oocytes were exposed to the hormone in the presence of theophylline. Theophylline, a competitive inhibitor of cyclic nucleotide phosphodiesterase, was present at 2.0 mM during a 30 min preincubation, as well as during exposure to hormone, and continuously for the duration of the experiment. At this concentration, theophylline inhibited GVBD and subsequent maturation in 100% of the oocytes in control

groups. Theophylline inhibited the decrease in cyclic AMP levels, but in contrast did not inhibit the decrease in cyclic GMP levels after exposure to progesterone (Fig. 2).

The inhibitory effects of cyclic AMP and theophylline on maturation¹ and of theophylline on the initial decrease in cyclic AMP levels after exposure to progesterone suggest that a decrease in the intracellular levels of this cyclic nucleotide is an early and necessary response of the oocyte in the induction of maturation by the steroid. Without characterising the oocyte adenylate cyclase and cyclic AMP phosphodiesterase(s), the data do not distinguish between activation of a phosphodiesterase and inhibition of adenylate cyclase as the event resulting in the observed decrease in cyclic AMP levels.

The failure of 2.0 mM theophylline to block the decline in cyclic GMP levels after hormone exposure suggests that this cyclic nucleotide is metabolised in a manner different from that of cyclic AMP. Alternatively, the sub-cellular distribution or kinetic properties of cyclic GMP phosphodiesterase different from those of cyclic AMP phosphodiesterase could be responsible for this result.

Cyclic nucleotide fluctuations are thought to influence cellular processes primarily through alterations in the activity of protein kinases^{21,22}. Increases in protein phosphorylation occur at GVBD in both *R. pipiens* and *X. laevis* oocytes^{23,24}. Maller and Krebs²⁵, using micro-injection techniques, have shown that the regulatory subunit of protein kinase mimics progesterone by inducing maturation of *X. laevis* oocytes, while the catalytic subunit inhibits progesterone induced maturation. These results suggest that a decrease in the catalytic activity of oocyte protein kinase is a key step in the induction process in *X. laevis*, and are consistent with a decrease in cyclic AMP levels after exposure of *X. laevis* oocytes to progesterone, similar to that which we report here for *R. pipiens*.

This study of the isolated *R. pipiens* oocyte has revealed a novel mode of steroid action: progesterone causes a reduction in intracellular levels of cyclic AMP that is essential to release of the oocyte from prophase arrest. The significance of very high levels of cyclic GMP relative to cyclic AMP in these cells, and of the later cyclic nucleotide fluctuations have not been determined.

We thank Drs J. K. Reyhout and F. G. Rothman for assistance, Drs M. J. Birnbaum and F. T. Marin for discussions and criticism, and Drs A. B. Kostellow and G. A. Morrill for communication of unpublished results. This work was supported by the Cystic Fibrosis Foundation, the USPHS and NSF. F.R.B. is the recipient of a Research Career Development Award from the USPHS.

Prostacyclin increases cyclic AMP levels and adenylate cyclase activity in platelets

PROSTACYCLIN (PGX) (ref. 1) is the name proposed for the metabolic product of a recently discovered enzymic transformation of the prostaglandin endoperoxides PGG_2 and PGH_2 (refs 2-4). Prostacyclin synthetase, the enzyme which catalyses this conversion, is particularly active in the microsomal fraction of blood vessel walls^{1,4} although there is evidence that it is also present in the rat stomach fundus². The prostaglandin endoperoxides, PGG_2 and PGH_2 , have been shown to contract arterial smooth muscle and to cause platelet aggregation^{5,6}, whereas, in contrast, prostacyclin relaxes arterial strips and prevents platelets aggregation⁷. A biochemical interaction has therefore been postulated to exist between platelets and the blood vessels wall, such that endoperoxides derived from platelets are converted by the vessel wall into prostacyclin, which in turn actively prevents the deposition of platelets on the vascular endothelium^{2,4}. In general, agents which inhibit platelet aggregation, such as PGE_1 , increase cyclic AMP levels, whereas agents causing aggregation lower platelet cyclic AMP levels⁷. The ability of prostacyclin to rapidly reverse or prevent platelet aggregation suggested that its action on the platelet might, like that of PGE_1 , be mediated by an increase in cyclic AMP levels. This hypothesis is supported by the experiments detailed here which strongly suggest that prostacyclin generated by incubation of arachidonic acid, platelets and aortic tissue, causes a rapid and pronounced accumulation of cyclic AMP by intact platelets, as well as stimulation of adenylate cyclase in isolated platelet membranes.

Human platelet-rich plasma (PRP) was incubated in the presence of theophylline, arachidonic acid, and chopped pieces of pig aorta obtained fresh from a local abattoir. Incubation conditions were similar to those used to generate prostacyclin in incubations of PRP with vascular rings⁸. Cyclic AMP was assayed in samples of incubation media at timed intervals. In the presence of arachidonic acid and aortic pieces, the cyclic AMP content of PRP rose approximately 12-fold within 5 min (Fig. 1a), declining gradually over the next 25 min. In the absence of aortic pieces, arachidonic acid produced no change in platelet cyclic AMP levels. No changes were observed in the cyclic AMP content of platelet-poor plasma (PPP) incubated in the presence of arachidonic acid and aortic rings. When arachidonic acid was omitted from the incubation medium, or the platelet-rich plasma was pre-incubated for 15 min with $100 \mu\text{g ml}^{-1}$ indomethacin, the changes in the cyclic AMP content of PRP were very much diminished, in one case presumably because substrate was absent, and in the other because the inhibition of cyclooxygenase by indomethacin led to reduced prostaglandin endoperoxide levels (Fig. 1b). In some experiments aortic pieces were incubated for 15 min with indomethacin and washed before incubation with PRP and arachidonic acid. This treatment did not alter the effect of aortic tissue on cyclic

Fig. 1 Cyclic AMP generation by platelets from arachidonic acid in the presence and absence of aortic tissue. PRP was prepared by centrifuging venous blood (9 volumes: 1 volume 3.8% citrate) at 500 g for 10 min at room temperature; PPP was obtained by centrifuging PRP at 5,000 g for 10 min. Reactions were begun by adding 4 ml of PRP or PPP to incubation flasks containing 2 ml buffer (15 mM Tris, pH 7.4, with 120 mM NaCl, 4 mM KCl, 1.6 mM MgSO_4 , 2 mM NaH_2PO_4 , 10 mM glucose and 0.2% bovine serum albumin) and theophylline (10 mM final concentration). Final concentrations of other components of the incubation medium were as follows: fresh pig aortic pieces (50 mg ml^{-1}), arachidonic acid (Sigma; AA, $10 \mu\text{g ml}^{-1}$). Where stated, PRP was pre-incubated for 15 min with indomethacin (I; $10 \mu\text{g ml}^{-1}$). 500 μl samples of incubation media were taken at intervals, boiled for 2 min, and the cyclic AMP content measured using beef adrenal protein kinase competitive binding assay⁹. Standard curves included an appropriate amount of a mixture of buffer and PPP depleted of cyclic AMP by standing overnight at room temperature. Assays were carried out in triplicate on single samples obtained at the indicated time points. The cyclic AMP content of the mixture of buffer and PPP was assayed and the results corrected for this value. a, PRP+AA and aortic pieces ($\circ$); PRP+AA ($\square$); PPP+AA+aortic pieces ($\bullet$). b, PRP+aortic pieces ($\blacksquare$); PRP (+I)+AA+aortic pieces ($\blacktriangle$). c, PRP+AA+aortic pieces+U44069 ($\circ$); PRP+AA+aortic pieces+U46619 ($\square$). d, PRP+aortic pieces+U44069 ($\bullet$); PRP+aortic pieces+U46619 ($\blacksquare$).

AMP levels (results not shown) and is consistent with the reported resistance of prostacyclin synthetase to inhibition by indomethacin. These results are consistent with the view that prostaglandin endoperoxides, intermediates in the metabolism of arachidonic acid by platelets, were converted in the presence of the aortic pieces to a substance which caused an immediate, pronounced rise in platelet cyclic AMP content. The same conditions, used by Bunting *et al.*⁴, resulted in formation of prostacyclin, a potent inhibitor of platelet aggregation.

The prostaglandin endoperoxide analogues (15S)-hydroxy-9 α , 11 α (epoxymethano) prosta 5Z-13E-dienoic acid (U44069) and (15S)-hydroxy-11 α , 9 α (epoxymethano)-prosta 5Z-13E-dienoic acid (U46619) had no influence on prostacyclin formation during the incubation of PRP with aortic rings (Fig. 1c, d), suggesting that as expected, these analogues were not used as substrates by prostacyclin synthetase and neither had any inhibitory effect on the enzyme. But, the addition of an aggregating agent—either

ADP or adrenaline—caused a marked decline in prostacyclin-stimulated platelet cyclic AMP levels (Fig. 2a). This effect was comparable to that of ADP or adrenaline on platelet cyclic AMP levels previously elevated by treatment with prostaglandin E_1 , and the mechanism may be that ADP and adrenaline directly stimulate phosphodiesterase in platelet membranes⁸. The stimulation of cyclic AMP formation during incubation of PRP with arachidonic acid and aortic fragments was prevented by including tranilcypromine (500 μ M) or oxidised arachidonic acid (10 μ g ml^{-1}) (Fig. 2b). Each of these substances has been shown to inhibit the activity of prostacyclin synthetase³.

A sample of incubation mixture of PRP, arachidonic acid and aortic pieces stimulated the activity of adenylate cyclase in partially purified platelet membranes (Fig. 3). Thus, the elevation by prostacyclin of platelet cyclic AMP levels, via the activation of platelet membrane adenylate cyclase, resembles the effects of PGE_1 and may account for the anti-aggregating property of prostacyclin previously demonstrated by Gryglewski *et al.*³. This conclusion receives support now from the demonstration that chemically synthesised prostacyclin is many times more active than PGD_2 and PGE_1 in stimulating platelet production of cyclic AMP and platelet membrane adenylate cyclase^{12,13}.

Involvement of cyclic AMP as an intermediate in prostacyclin action provides a biochemical basis for an important

Fig. 2a Effects of ADP and adrenaline on accumulation of cyclic AMP by platelets. Incubations were carried out as described for Fig. 1, and contained PRP in buffer, AA (10 μ g ml^{-1}) and aortic rings (50 mg ml^{-1}). At the time indicated by the arrow, ADP (10 μ g ml^{-1} ; $\square$) or adrenaline (10 μ g ml^{-1} ; $\triangle$) or buffer ($\circ$) was added, and sampling for cyclic AMP assay continued. **b**, Effects of tranilcypromine and of oxidised arachidonic acid on cyclic AMP accumulation by platelets in the presence of aortic pieces. Arachidonic acid was oxidised by dissolving it in buffer at 10 μ g ml^{-1} and exposing it to a stream of air overnight at 25 °C. Incubations were carried out as described in Fig. 1. PRP + aortic pieces + AA ($\circ$); PRP + aortic pieces + AA + tranilcypromine (0.5 mM) ($\square$); PRP + aortic pieces + AA + oxidised arachidonic acid (10 μ g ml^{-1}) ($\triangle$). Assays were carried out in triplicate on single samples obtained at the indicated time points.

Fig. 3 Adenylate cyclase activity in crude platelet plasma membranes. Platelets were centrifuged from PRP at 5,000 g for 10 min, the platelet pellet disrupted by rapid freezing and thawing (three times) and the crude membrane fraction harvested by centrifuging at 10,000 g . Adenylate cyclase incubations were carried out in 2 ml volumes of 25 mM Tris HCl containing 1 mM ATP³² (10 c.p.m. pmol⁻¹), 4.5 mM $MgCl_2$, 30 mM KCl, 1.5 IU pyruvate kinase; 2 mM phosphoenolpyruvate; 0.013% bovine serum albumin, and platelet membranes. After starting the reactions by addition of platelet membranes, 100- μ l samples were removed at the intervals shown, added to 10 μ l of 40 mM ATP and boiled immediately. The generated ³²P-cyclic AMP was purified by sequential chromatography on Dowex and alumina^{10,11}. At the time indicated by the arrow further additions were made to each flask as follows: $\bullet$, 100 μ l from a 6-ml incubation of PRP, AA (10 μ g ml^{-1}) and aortic rings (50 mg ml^{-1}) which had been incubating for 5 min (see Fig. 1a); $\circ$, 100 μ l from a 6-ml incubation of PPP and AA (10 μ g ml^{-1}) which had been incubating for 5 min (see Fig. 1a).

cellular control system, which produces cooperation between the vascular wall and the blood platelet in order to prevent platelet adhesion to vascular endothelium. In this homeostatic mechanism, the prostacyclin could act continuously upon the platelets to increase cyclic AMP, which in turn may inhibit the platelet cyclooxygenase¹⁴, thereby limiting the amount of endoperoxide available for thromboxane synthesis, and thus turning off production of these potent short-lived stimulators of platelet aggregation. If prostacyclin or related compounds are found to be produced in other tissues, studies of their effects on target tissues will be greatly facilitated if they are found to have the general property of stimulating adenylate cyclase activity.

Calcium-dependent somatostatin secretion from rat neurohypophysis *in vitro*

THE tetradecapeptide somatostatin originally identified in hypothalamic extracts, has been subsequently shown by bioassay, radioimmunoassay and immunohistochemical techniques to be extensively distributed throughout the central nervous system, in the gastrointestinal tract, and in the pancreas¹⁻⁵. Within the central nervous system, immunoreactive somatostatin has been localised to fibres in the external zone of the median eminence, to neuronal cell bodies in the anterior hypothalamus, to axons in the posterior pituitary lobe, as well as in spinal ganglia and in fibres in the dorsal zone of the spinal cord⁶. Although strong indirect evidence exists for the release of somatostatin from the hypothalamus into the portal vessels in physiological conditions⁷ there are no direct studies of somatostatin secretion from nerve cells. Since the neurohypophysis contains a high concentration of somatostatin⁸, and can be readily isolated, we used it as a model for studying the *in vitro* release of the peptide from nerve terminals. We report that secretion is markedly increased following potassium stimulation, provided calcium is present in the incubation medium.

Male Sprague-Dawley rats (240-300 g) were killed by decapitation, the posterior pituitary lobes were isolated, separated from adhering intermediate lobe tissues and incubated in pools of five in 1 ml bicarbonate-buffered Locke's solution at 37 °C under an atmosphere of 95% O₂-5% CO₂ with constant shaking. After a 30 min preincubation period, the medium was replaced by fresh Locke's solution or a modified Locke's solution at 30 min intervals. Medium from each incubation period was collected in glass tubes at 0 °C. On completion of each experiment the neural lobes were extracted by sonication in 1 ml 1-M acetic acid. Media and extracts were measured for somatostatin by a specific radioimmunoassay⁹ with a mean sensitivity of 1.4 pg. The protein content of the extracts was determined by the method of Lowry *et al.*¹⁰.

A high concentration of immunoreactive somatostatin was found in the posterior pituitary extracts. This contrasts with the absence of somatostatin in the anterior pituitary⁸. The total neurohypophysial content of somatostatin was determined by adding the amount of immunoreactivity released in the incubation media to the content remaining in the neurohypophysial lobes at the end of the experiment and yielded a value of 773±64 pg per neural lobe (mean±s.e.m. of 84 pools of five lobes each) or a concentration of 4.9±0.4 pg per µg protein. Somatostatin was secreted at a low basal rate from the isolated neural lobes, the amount released 5.9±1.4 pg per neural lobe per 30 min, representing 1.4±0.35% of the total content (mean of 20 experiments, Fig. 1).

High extracellular potassium is a potent stimulus for neurohypophysial hormone secretion and this response can be potentiated by a lowering of the extracellular sodium ion concentration¹¹. The release of somatostatin was also markedly increased following potassium stimulation to 14.8% of total content per 30 min ($P<0.01$, Fig. 1a). This stimulatory effect was calcium dependent and was abolished

Fig. 1 Somatostatin-like immunoreactivity released by pools of five rat neural lobes during successive 30 min incubation periods. Each column represents the mean ± s.e.m. of 10 experiments. The initial incubation medium (first column in a and b) contained (in mM): Na⁺, 160; K⁺, 5.6; Ca²⁺, 2.2; Mg²⁺, 1.0; Cl⁻, 160; HCO₃⁻, 12 and glucose, 10. In a, the Na⁺-concentration of incubation medium was lowered to 12 mM for the second and third incubation periods; in addition, the K⁺-concentration was raised to 56 mM during the third period. Isoosmolarity was maintained by adding appropriate amounts of choline. In b, the same protocol was followed except that Ca²⁺ was replaced by Mn²⁺ (2.2 mM) during the second and third incubations. Values are expressed in % of total content of neurohypophysial somatostatin released per incubation period.

when extracellular Ca²⁺ was replaced by an equimolar concentration of Mn²⁺ an antagonist of Ca²⁺ in secretory processes (Fig. 1b, $P<0.01$).

The present studies confirm our earlier observation of the presence of immunoreactive somatostatin in the rat neurohypophysis⁸. Somatostatin thus represents a further addition to the list of peptides found in the posterior pituitary which includes oxytocin, vasopressin and thyrotrophin releasing hormone¹¹. Although the posterior pituitary concentration of somatostatin is comparable with that of other somatostatin rich neural tissues (for example, cerebral cortex, brain stem, spinal cord⁶) it is over 1,000 times lower than the concentration of the classical neurohypophysial hormones, oxytocin and vasopressin^{12,13}.

The mechanism of somatostatin release from the posterior pituitary shares two important characteristics with the neurosecretory process: stimulation of release in response to membrane depolarisation and dependence of this process on extracellular calcium. The functional significance of neurohypophysial somatostatin remains to be determined. One possibility is that somatostatin stimulates the release of vasopressin as suggested by *in vitro* studies¹⁴. Second, since somatostatin released in the posterior pituitary is capable of reaching the anterior pituitary through the short portal vessels, it seems likely that neurohypophysial somatostatin along with somatostatin released from the median eminence may have a role in the regulation of growth hormone and thyroid stimulating hormone secretion.

Brain thyrotrophin-releasing hormone is independent of the hypothalamus

THYROTROPHIN-releasing hormone (TRH) is widely distributed in regions of the brain outside the hypothalamus¹⁻³, and behavioural⁴ and neurophysiological⁵ studies lend credence to the hypothesis^{1,6} that in these locations it is involved in neurotransmission. To determine whether extrahypothalamic brain TRH arises from the hypothalamus or is synthesised *in situ*, we have made electrolytic lesions of the "thyrotrophic area"⁷ of the rat hypothalamus, and examined the effect on TRH content in the hypothalamus itself, the rest of the brain and the anterior and posterior pituitary. We have found that such lesions markedly reduce the hypothalamic content of TRH, deplete the pituitary gland of TRH and result in severe chemical hypothyroidism, but do not affect the large amount of TRH normally stored in the extrahypothalamic brain.

We placed bilateral electrolytic hypothalamic lesions with a platinum electrode (Stoelting lesion maker) (3mA for 30 s) in male Sprague-Dawley rats (Charles River) under ether anaesthesia. The coordinates⁸ chosen—AP 6.4 mm, lateral 0.7 mm on each side of midline, vertical +1.5 mm—were designed to produce a large lesion in the region of the paraventricular nucleus extending towards, but not involving, the median eminence or pituitary stalk. Such lesions produce marked impairment of pituitary-thyroid function⁹. Six out of nine animals survived the procedure. In the seven control rats bilateral electrolytic lesions were placed in the cerebral cortex 2 mm below the surface. Both groups weighed about 400 g.

The effectiveness of the procedure was assessed 1 week later by determination of serum thyroxine (T₄) by immunoassay on blood removed by orbital puncture from the rats under ether anaesthesia. T₄ levels in the lesioned rats were all lower than the values in the controls (mean $\pm$ s.e.m.) 0.7 ± 0.1 compared with 4.1 ± 0.4 $\mu\text{g dl}^{-1}$ ($P < 0.001$).

To obviate the effect of hypothyroidism *per se* on tissue TRH content, all animals (test and control) were given orally sodium-L-thyroxine ($12 \mu\text{g d}^{-1}$, a dose designed to provide normal thyroid replacement) in 20 ml of a synthetic liquid diet (Sustacal) for 14 d, the last dose of thyroxine being given 48 h before termination of the experiment. The animals were decapitated and the brains were removed immediately. The hypothalamic lesions were confirmed visually with the aid of a dissecting

microscope, and hypothalami from both groups were excised and placed in 2 ml of 90% methanol for extraction; the anterior and posterior pituitaries were treated similarly. Tissue taken for the hypothalamic fragment was bounded anteriorly by the optic chiasm, posteriorly by the anterior margin of the mammillary nucleus, laterally by the hypothalamic sulcus and dorsally by a plane connecting the anterior commissure and anterior margin of the mammillary nucleus. To extract TRH from the brain, it was extruded through a 21-gauge needle into 10 ml of 90% methanol. The dried methanol extracts of all the tissues were reconstituted in phospho-saline buffer and assayed for TRH by a specific radioimmunoassay as before¹.

Although the hypothalamic content of TRH was much reduced in the lesioned rats compared with controls ($3,625 \pm 249$ compared with $9,357 \pm 449$ pg; $P < 0.001$), the amount of TRH in the extrahypothalamic brain ($17,040 \pm 925$ compared with $18,929 \pm 737$ pg) was similar in both groups; indeed the concentration of TRH was identical in the lesioned and normal animals (70 pg per mg protein¹⁰). In contrast the TRH content was markedly lower in the anterior pituitary (15 ± 8 compared with 64 ± 5 pg; $P < 0.001$) and posterior pituitary (< 2 compared with 157 ± 32 pg; $P < 0.001$) (Table 1). The lower TRH in anterior pituitary likely resulted because less TRH was delivered to the pituitary.

Table 1 Effect of a lesion of the 'thyrotrophic area' of the hypothalamus on brain distribution of TRH in the rat

	Lesion	Control	Significance
Hypothalamus	$3,625 \pm 249$	$9,357 \pm 449$	$P < 0.001$
Anterior pituitary	15 ± 8	64 ± 5	$P < 0.001$
Posterior pituitary	< 2	157 ± 32	$P < 0.001$
Extrahypothalamic brain	$17,040 \pm 925$	$18,929 \pm 737$	$P > 0.1$

Results (mean $\pm$ s.e.m.) are given as pg per tissue. Six lesioned and seven control animals were studied.

This study shows that a lesion of the hypothalamus resulting in reduced hypothalamic content of TRH and impaired TRH secretion from the hypothalamus, as implied from the low circulating levels of thyroxine, does not affect extrahypothalamic brain TRH content, suggesting that the latter is synthesised *in situ* and is independent of the hypothalamic secretion. Complementary studies were done by Brownstein *et al.*¹¹ who showed that after hypothalamic deafferentation the extrahypothalamic brain TRH content was unaltered whereas the hypothalamic TRH content was reduced, raising the possibility that much of the hypothalamic TRH is synthesised by cells outside this region.

The high concentration of TRH in the posterior pituitary relative to the anterior pituitary in the normal group (560 ± 9 compared with 28 ± 2 pg per mg protein; $P < 0.001$) has been observed before^{1,3}. The depletion of TRH from the posterior pituitary in the lesioned animals supports the concept of a third neurosecretory hypothalamo-hypophyseal system extending into the neurohypophysis, as suggested by Hökfelt *et al.*¹² on the basis of immunohistochemical staining of TRH¹³ and somatostatin¹⁴ positive fibres reaching into the posterior pituitary from the median eminence. Whether TRH has a role in posterior pituitary function is uncertain, but it may be relevant that TRH is found in high concentrations in the pituitary complex of lower vertebrates¹, and there is evidence (reviewed by Sawyer¹⁴) that in the bony fish the neurohypophysis may be an homologue of the median eminence in higher animals.

We thank Mrs Faye SooHoo for technical assistance. This study was supported by a grant from the NIH.

Synaptic responses mediated by identified histamine-containing neurones

EFFORTS to prove that histamine has a role in synaptic neurotransmission have been less successful than for other biogenic amines. For example, there has been no convincing physiological or pharmacological evidence to support the transmitter candidacy of this imidazole at any known synapse. In the central nervous system (CNS) of the marine mollusc *Aplysia californica* chemical measurements of single isolated neurones have revealed large concentrations of histamine within two identified neurones¹. The histamine-containing neurones (HN) uniquely possess a specific histidine decarboxylating enzyme and they can synthesise and store labelled histamine². These biochemical observations prompted the suggestion³ that the two identified nerve cells utilise histamine as a neurotransmitter. The physiological studies reported here show that each HN monosynaptically elicits multicomponent excitatory and inhibitory postsynaptic potentials (p.s.ps) in different follower neurones, the somal membranes of which show appropriate potential changes to iontophoretic application of histamine. This suggests that histamine is a neurotransmitter released from the nerve terminals of the HN.

In the absence of ultrastructural evidence needed to prove the monosynaptic nature of cell-to-cell connectivity, several physiological criteria provide a reliable basis on

which to distinguish between direct and indirect synaptic connections (reviewed in ref. 3). These criteria include: (1) that the postsynaptic response follows the presynaptic action potential in a one-for-one manner and that there is a constant latency of response; (2) that the postsynaptic responses persist in medium containing increased concentrations of Ca^{2+} , and (3) that synaptic efficacy increases after intracellular injection of tetraethylammonium (TEA) into the presynaptic neurone. These tests have been applied in the work reported here to support the monosynaptic character of synaptic responses elicited by the HN.

Desheathed cerebral ganglia dissected from *Aplysia* (200-350 g) were perfused with artificial seawater (ASW, 492 mM, NaCl; 10 mM, KCl; 20 mM, MgCl_2 ; 30 mM, MgSO_4 ; 60 mM, CaCl_2 ; 10 mM, Tris). The pH of the ASW was adjusted to 7.8 and the temperature was maintained at 18 °C by a Peltier device. Standard electrophysiological techniques were used for intracellular stimulation and recording with double-barrelled glass microelectrodes filled with 2 M potassium citrate or 3 M TEA bromide. In several experiments the identity of the HN was biochemically confirmed after intracellular recording from pre- and post-synaptic neurones by assaying the activity of histidine decarboxylase, which is a cell-specific marker for HN in *Aplysia*⁴.

In either normal or Ca^{2+} -enriched ASW solutions the HN are silent, displaying little spontaneous synaptic and action potential activity. Several identifiable neurones located on the dorsal surface of the ganglion showed consistent synaptic effects after action potentials evoked in the HN. These follower neurones are symmetrically located on both the left and right sides of the ganglion: they show (1) identical responses to ipsilateral HN stimulation, (2) similar spontaneous synaptic and action potential rhythms and (3) antidromic responses to electrical stimulation of the corresponding ipsilateral and contralateral cerebral nerve trunks. No synaptic responses could be observed between left and right HN nor between ipsilateral HN and contralateral follower neurones; intracellular dye (ccalt) injection also indicates that neither the HN nor the follower neurones send axons across the midline of the ganglion (my unpublished observations).

Fig. 1 Inhibitory effects produced by histamine-containing neurone (HN) spikes on one class of follower neurones. *a*, Inhibition of spontaneous spike activity in a follower neurone evoked by HN spikes. *b*, Inhibitory response to iontophoretic application (30 nA, 0.5 s) of histamine (HA) delivered to the somal membrane of the same follower cell; action potential amplitudes smaller than in (*a*) due to frequency response characteristics of the recording channel. *c*, i.p.s.ps recorded after spontaneous spiking was prevented by pre-setting the membrane potential to -55 mV. Right trace shows i.p.s.p. 5 min after TEA was injected into the HN by passing current between two intracellular TEA electrodes. Inflection point on the rising phase (arrow) of the i.p.s.p. depicts the fast phase of the two-component i.p.s.p. *d* and *e*, Fast i.p.s.ps recorded in a similar follower neurone from another cerebral ganglion at 4 °C to abolish the slow i.p.s.p.; membrane potential preset to about -50 mV. *d*, Association between HN spikes and fast i.p.s.ps; *e*, six superimposed records of fast i.p.s.ps and HN spikes illustrating constant latency of the evoked i.p.s.p.; latency of fast i.p.s.p. exaggerated by cooling. In this and subsequent figures upper voltage calibrations are associated with upper traces (follower neurones); lower voltage calibration corresponds with lower traces (HN).

Figure 1a shows the effects produced by a train of HN spikes on the endogenous activity of one class of follower neurones. At the normal resting potential, about -50 mV, as few as five HN spikes rapidly depress spontaneous spiking activity in these neurones. Thus the influence of the HN on these follower cells is clearly inhibitory. Spiking activity in the follower neurones was also inhibited by iontophoretic application of histamine (Fig. 1b), suggesting that histamine receptors are present on these postsynaptic membranes. When the membrane potential of the follower neurone was hyperpolarised beyond spiking threshold, hyperpolarising p.s.ps (i.p.s.ps) were observed. These are composed of two components, an initial rapid i.p.s.p. with a fast rise time and short duration (200–400 ms) and a slow i.p.s.p. with a gradual rise time and a prolonged decay phase (several seconds). The amplitude of the fast i.p.s.p. is usually small at membrane potentials near -60 mV and frequently obscured by the slow i.p.s.p. The fast i.p.s.p. becomes evident, however, when transmitter release from the HN is potentiated by intracellular administration of TEA or by cooling the preparation below 7°C , which reversibly suppresses the slow i.p.s.p. Figure 1c shows the i.p.s.ps before and 5 min after injection of TEA when the duration of the presynaptic action potential had more than doubled and the i.p.s.ps were substantially increased in duration and amplitude. The one-to-one nature of the fast i.p.s.p. and its constant latency at 4°C are illustrated in Fig. 1d and e, respectively. In other experiments where the slow i.p.s.p. was also eliminated by cooling, it was possible to reverse the polarity of the fast i.p.s.ps at membrane potentials greater than -65 mV (E_{Cl}) (ref. 4). Thus, the sensitivity to cooling of the slow i.p.s.ps, a known characteristic

of potassium-dependent potentials in *Aplysia*⁴, and the polarity change of the fast i.p.s.p. below -65 mV suggest that these fast and slow i.p.s.ps are mediated by chloride and potassium conductances, respectively.

Another class of postsynaptic response is illustrated in Fig. 2. Endogenous spiking activity in these follower neurones was inhibited by HN stimulation and by the application of histamine. Although these followers are functionally inhibited by spike activity in the HN, a small excitatory component always precedes the hyperpolarising response. This early component is more apparent when the membrane potential of the follower neurone is polarised to prevent spiking. The sample records shown in Fig. 2 b–d illustrate the postsynaptic responses at greater amplification and at different membrane potentials. When the membrane potential was increased, the excitatory component (arrows) became more prominent and at -80 mV the response was almost entirely excitatory. Similarly, the hyperpolarising response to exogenously applied histamine decreased and at -80 mV the histamine response was biphasic. Thus it seems that two types of histamine receptors may exist on the membranes of these follower neurones, one mediating a hyperpolarising response and the other associated with depolarisation. The biphasic nature of the p.s.ps is further illustrated in Fig. 2e–h when the membrane potential of the follower neurone was preset to -60 and -90 mV. The synaptic responses shown reveal several characteristics of these biphasic responses: (1) they are composed of a rapid (200–400 ms) depolarising component (e.p.s.p.) and a slowly developing and prolonged (s) i.p.s.p.; (2) the equilibrium potential of the i.p.s.p. is near -80 mV because it was reversed in polarity at -90 mV

Fig. 2 Biphasic responses in another class of follower neurones. a, Effects of trains of HN spikes and the application of histamine (HA) on spontaneous spiking activity of the follower neurone recorded at resting potential (-45 mV), histamine applied by diffusion from a micropipette. b–d, Effects of HN spikes and histamine recorded at various membrane potentials shown in each set; arrows indicate the onset of the early excitatory synaptic component of the evoked response. e–g, Biphasic p.s.ps recorded at different membrane potentials and after various numbers of HN spikes. h, Biphasic p.s.p. 30 min after TEA was intracellularly injected into the HN; insets near lower traces show duration of HN spikes before (e) and 30 min after TEA administration (h). All records from the same follower neurone.

Fig. 3 Excitatory responses elicited by HN stimulation. *a*, Effects of three HN spikes on the endogenous activity of a follower neurone. *b*, Excitatory responses to iontophoretic application (20 nA, 0.5 s) of histamine (HA) delivered to the somal membrane of another follower neurone receiving excitatory synaptic input from HN. *c*, Four superimposed traces of e.p.s.ps and HN spikes recorded from the same follower as illustrated in (*b*). *d-f*, Effects produced by intracellular TEA into the HN in another preparation bathed in ASW containing normal (10 mM) Ca^{2+} ; membrane potential preset to -55 mV. *d*, Control responses; *e* and *f*, obtained at times indicated after administration of TEA. At 20 min after injection, two HN spikes produce fast and slow e.p.s.ps, with amplitude and duration substantially larger than control response to a train of seven HN spikes. E.p.s.ps in *d* and *e* cause firing of the follower neurone.

(Fig. 2g) and nearly absent at -80 mV (Fig. 2d); and (3) the amplitude of the i.p.s.ps, unlike those of the e.p.s.ps, were potentiated by repetitive firing of the HN (compare traces *f* and *g* in Fig. 2). Figure 2h shows the increased HN spike duration and the accompanying increases in the amplitudes and durations of both e.p.s.p. and i.p.s.p. components of the biphasic p.s.p. 30 min after TEA injection.

In a third class of follower neurones, stimulation of the HN produced excitatory responses, that is an increase in the rate of spiking (Fig. 3a); these followers also show an excitatory response to iontophoretically applied histamine (Fig. 3c). Like the two previously described synaptic responses, these excitatory followers also received two-component p.s.ps—a fast depolarising component (fast e.p.s.p.) several hundred milliseconds in duration and a long-lasting (seconds) depolarising component (slow e.p.s.p.). The sample records shown in Fig. 3c illustrate the constant latency between the HN spikes and the fast e.p.s.p. The two-component nature of these excitatory synaptic responses is clearly observed when transmitter release is enhanced by prolonging the HN spike by injection of TEA or by lowering the temperature of the bathing medium (data not shown). The responses shown in Fig. 3d–f reveal the effects of intracellular injection of TEA on the e.p.s.ps recorded from another preparation bathed in normal ASW (10 mM Ca^{2+}). Ten minutes after injection the amplitude and duration of both fast and slow e.p.s.ps were substantially increased and by 20 min the responses were even further potentiated.

These results demonstrate that single HN excite some follower neurones and inhibit others, and that the synaptic potentials underlying these effects are multicomponent, consisting of fast and slow p.s.ps in various combinations: fast i.p.s.p.+slow i.p.s.p.; fast e.p.s.p.+slow i.p.s.p.; and fast e.p.s.p.+slow e.p.s.p. Multiphasic p.s.ps elicited by single presynaptic neurones are not an uncommon feature of molluscan synapses^{6–11}, and multi-receptor systems for proven or suspected neurotransmitters have been characterised on molluscan neurones^{12–15}. The tests used to distinguish between polysynaptic and monosynaptic connections indicate that all synaptic responses evoked by HN are mediated by monosynaptic pathways. Even though the measurements of latency and constancy of the slow synaptic responses are compromised by their gradual onset and long duration, the persistence of the slow p.s.ps. in high- Ca^{2+} ASW and their enhancement produced by intracellular injection of TEA is consistent with the monosynaptic nature of these slow responses.

The observations that neurones receiving monosynaptic connections from the HN respond to exogenously applied histamine in a manner qualitatively similar to the effects produced by HN stimulation demonstrates that histamine could act as a neurotransmitter at these identified synapses. This view is strengthened by the observations that histamine-sensitive neurones are but a small fraction of the neurones within this nervous system (ref. 16 and my unpublished results). Thus from the results described here together with previous biochemical data^{1,2} showing that these same presynaptic neurones uniquely synthesise and contain substantial amounts of histamine, it seems that this system of identifiable nerve cells will be useful for clarifying whether histamine is actually released as a synaptic neurotransmitter.

I thank the NSF for financial support and Dr N. Brookes for helpful discussions and criticism of the manuscript.

Reduced β -adrenergic receptor concentrations in ageing man

CONCENTRATIONS of certain hormone receptors are known to be reduced during ageing in several animal species^{1–4}. Most relevant work, however, has been limited to intracellular hormone receptors such as those for steroids, and less is known about changes in cell surface receptors, including those for catecholamines. We have measured the concentration of β -adrenergic receptors in crude membrane fractions of mononuclear cells from human subjects of various ages. Receptor affinities for ($-$) ^3H -dihydroalprenolol were essentially the same for all subjects. But a

significant decrease in receptor concentration was observed in cells from older individuals.

Subjects were 23 males between 24 and 81 yr old, without significant illnesses and taking no medications. Some were paid volunteers and others were recruited from the longitudinal study of ageing of the National Institute on Ageing and thus were living in a community and fully ambulatory. The study lasted 6 months with a random distribution of subjects by age. We made multiple determinations of receptor concentrations on several subjects during 2–3 months. Subjects fasted and did not smoke for 12 h before the study. With written consent, 112–225 ml of blood was withdrawn by antecubital venipuncture into heparinised syringes, with subjects in the supine position. Whole blood was subjected to density gradient centrifugation by the method of Böyum, using a Ficoll-diatrizoate mixture (specific gravity 1.077)⁵. Mononuclear cell fractions thus obtained were assayed for β -adrenergic receptors by a modification of the method of Williams *et al.*⁶. This method uses the labelled β -adrenergic antagonist (–)³H-dihydroalprenolol incubated at various concentrations (10^{-8} to 10^{-7} M) with washed crude membrane preparations in the presence and absence of 10^{-3} M unlabelled (–) dihydroalprenolol to determine specific binding. Numbers of lymphocytes were determined by morphological criteria using Turks solution and the nonspecific esterase staining technique adapted from Yam *et al.*⁷. Cell viability was evaluated by Trypan blue exclusion. Protein determinations were made by the method of Lowry *et al.*⁸.

The specific binding of (–)³H-dihydroalprenolol to the washed crude membrane preparation was saturable, of high affinity and stereospecific in favour of the (–) stereoisomer. These findings are consistent with those of Williams *et al.*, who showed that binding detected by this method possesses the characteristics of the β -adrenergic receptor⁶. Lymphocytes constituted 83% of the mononuclear cells obtained. Viability as assessed by Trypan blue exclusion was generally greater than 94%. Cell yield, cell viability and protein yield per cell did not vary with the age of the donor. Saturation plots of β -adrenergic receptor concentrations in crude mononuclear membrane preparations of two representative subjects are shown in Fig. 1. At saturation levels (greater than 5×10^{-8} M (–)³H-dihydroalprenolol) specific binding accounted for approximately 50% of total binding, although at lower concentrations the percentage of specific binding was greater, as reported by Williams *et al.*⁶.

The receptor has high affinity for (–)³H-dihydroalprenolol in preparations from both young and old subjects, with K_{DS} of approximately 20 nM for each group. The mean saturation level of young subjects (24–41 yr, $n = 11$), however, was 572 ± 58 pmol mg⁻¹ protein ($\pm$ s.e.m.) while for subjects older than 46 yr ($n = 12$) the corresponding value was slightly greater than half that value,

Fig. 1 Specific binding of (–)³H-dihydroalprenolol to crude mononuclear cell membranes of representative subjects. ●, 24-yr-old; ○, 75-yr-old.

332 ± 48 pmol mg⁻¹ protein ($\pm$ s.e.m. $P < 0.01$). When all data are considered (Fig. 2), there is a significant negative correlation of receptor concentration with age ($r = 0.641$, $P < 0.001$).

Receptor number per cell also correlated inversely with age from approximately 14,000 to 8,000 sites per cell in the young and old groups, respectively. Receptor levels in individual subjects remained fairly constant over short periods (2–3 months).

Fig. 2 Maximal specific binding of (–)³H-dihydroalprenolol to crude mononuclear cell membranes of subjects aged 24–81 yr.

The search for physiological and biochemical determinants of ageing has led to investigations of age-associated alterations in hormone receptors. Steroid receptor concentrations are known to decline with age in various rodent tissues^{1,2,4,9,11}, and the ability of steroid hormones to elicit physiological responses has been shown to be diminished with age in several of these tissues^{1,10,11}. Whereas steroid hormone receptors are intracellular, some receptors located on the cell surface also seem to change with age. Concentrations of rat hepatic insulin receptors and adipocyte glucagon receptors, however, seem to decline very early in life^{12,13}.

Previous work with human material has dealt with either intracellular receptors or cells in tissue culture. Binding of glucocorticoids to intracellular receptors in human liver obtained postmortem is diminished in older individuals³. The effect of age on binding of insulin to cultured human fibroblasts has also been studied, but the results have been controversial^{14,15}. Our investigation is the first to demonstrate age-associated alterations of surface hormone receptors in cells taken directly from man.

The aetiology of these receptor alterations remains unclear. Differences in the composition of mononuclear cell populations or individual changes in the mononuclear cells might result in variation between young and old individuals. Relative and absolute numbers of T and B lymphocytes have been thought to remain fairly stable during human ageing^{16,17}, but this has been questioned⁸. Selective removal of monocytes from the mononuclear cell preparation by a nylon mesh column does not markedly influence the amount of (–)³H-dihydroalprenolol specifically bound⁶. The values obtained for the concentration of β -adrenergic receptors of young (age 24–41 yr) subjects, while higher than those initially published⁶, compares more closely with values currently obtained using similar methods (ranging from 96 to 476 fmol (–)³H-dihydroalprenolol specifically bound per mg protein) (personal communication from K. Kariman and R. J. Lefkowitz). Additionally, diminished concentrations of β -adrenergic receptors have been reported in frog erythrocyte membranes previously

exposed to catecholamines *in vivo*¹⁹. This catecholamine-induced 'desensitisation' is another possible aetiology for receptor decline in ageing man, where plasma catecholamine levels are known to increase²⁰.

Altered responsiveness to catecholamines has been observed during ageing in several rodent and human organ systems as well as in intact man²¹⁻²⁴. Several immunological functions of lymphocytes are known to be influenced by adrenergic agents²⁵. The possible role of age-associated receptor reduction or 'desensitisation' in altering the effects of catecholamines on these functions requires elucidation.

Our findings complement previous studies in several aspects. Our results lend further support to the idea that loss of certain hormone receptors is a frequent manifestation of ageing. The demonstration of diminished β -adrenergic receptor concentrations in ageing man offers a possible explanation for the observed age-associated loss of adrenergic responsiveness.

Tuning properties of cochlear hair cells

THE mammalian cochlea is generally considered to be a frequency analyser. When the ear is stimulated by a pure tone the basilar membrane vibrates. The amplitude of the vibrations varies along the length of the membrane with the position of the maximum depending in a graded way upon the frequency of the tone^{1,2}. The basal turn responds maximally to high frequencies, the apex to low frequencies. Consequently hair cells situated along the membrane are frequency selective. The nerve fibres innervating the basilar membrane have low thresholds over a narrow range of frequencies corresponding to the displacement maxima of the section of the basilar membrane that they innervate³. But the neural tuning curves (the relationship between threshold and frequency for individual nerve fibres) are much sharper than the mechanical tuning curves of the basilar membrane (the relationship between amplitude of displacement and frequency at a single point on the membrane) and this discrepancy has led to the proposal of a "second filter"⁴. In this paper we describe the tuning of intracellularly recorded receptor potentials from histologically identified hair cells (IHC) of the guinea pig cochlea

in an effort to investigate the nature of the hypothetical sharpening process and we conclude that IHCs are tuned as sharply as auditory nerve fibres. To our knowledge this is the first time intracellular recordings have been made from inner hair cells in the mammalian cochlea.

Guinea pigs weighing 120-200 g were maintained throughout the experiment under pentobarbitone-phenoperidine anaesthesia and were paralysed with Flaxedil (gallamine triethiodide) and artificially ventilated (method of E. F. Evans, personal communication). The cochlea was exposed ventrolaterally through the acoustic bulla. A fine Teflon insulated silver wire was positioned close to the round window and secured to the skull with cyanoacrylic cement so that the threshold (within 10 dB) of the compound action potential (AP) evoked by pure tone bursts of 2 ms duration could be monitored during the exposure of the basilar membrane. The sound source was a driven half-inch condenser microphone (B&K 4133) in a hollow ear bar which was inserted in the tympanic ring and secured to the temporal bone and adjacent bones with cyanoacrylic and dental cement. The basilar membrane of the basal turn was exposed taking care to minimise bleeding into the scala tympani thus preserving AP threshold. All results presented in this paper are uncorrected for the sound system which is measured to be flat within 10 dB. The sound pressure levels (SPL) indicated are referred to 0 dB SPL re 2×10^{-5} N m⁻².

Microelectrodes were drawn from 1 mm o.d. fibre filled boro-silicate glass tubing on a Livingstone type electrode puller. They had resistance of about 700 M Ω when filled with 6% procion yellow, but this was reduced to around 300-400 M Ω by bevelling the electrode tips (on a grinding wheel) to facilitate penetration of the basilar membrane⁵. Despite the reduction in their resistance by bevelling, the frequency response of the electrodes was too low to record cochlear microphonics and we have therefore concentrated on measuring the d.c. receptor potential (summing potential). The electrodes were advanced under visual control into the basilar membrane with a hydraulic micro-

Fig. 1 An inner hair cell (arrow) filled with Procion Yellow in the basal turn of the right cochlea of animal 128. The photomicrograph was taken with ultraviolet illumination and the scale bar indicates 25 μ m.

Fig. 2 *a*, Receptor potentials recorded intracellularly from an identified inner hair cell in the basal turn of the right cochlea of animal 105 in response to 15-ms tone bursts (rise and fall time 2 ms) presented at 470-Hz intervals. Trigger pulses for the tone bursts are shown in the lower trace beginning at 1 kHz and ending at 30.5 kHz. *b*, Isointensity curves of the receptor potentials shown in (*a*) plotted at their different SPL.

drive and were accurately positioned when the perilymph was momentarily drained. On rare occasions there was a transient rise in threshold after draining the scala tympani, however sensitivity always returned as the scala tympani refilled.⁶

The first two or three cells encountered by the micro-electrode in the region of the IHCs had resting potentials of 80–90 mV and small depolarising potentials of 0–1 mV at 74 dB SPL at characteristic frequency (CF). When the electrode was advanced further, cells were encountered with resting potentials between 35–45 mV and with positive receptor potentials between 5 and 17 mV at 74 dB SPL at CF; negative receptor potentials were never recorded intracellularly.

Membrane potentials were sometimes stable for 10 min or more, but on occasion dropped within a minute of penetration. The magnitude of the receptor potential seemed to vary with the amount of damage sustained by HCs during penetration and was not highly correlated with the AP threshold. Of 26 dye marked cells with large receptor potentials, nine were successfully found under the microscope and were identified as IHCs. An example is shown in Fig. 1. Only the data from these cells are discussed here.

The frequency response of the IHCs was determined between 1 and 40 kHz by presenting 15-ms tone bursts at 470-Hz intervals. At high SPL (74 dB), the frequency response is similar to that of the basilar membrane. However, as the SPL is reduced the receptor potentials at frequencies below the CF fall faster than those at the CF so that at 44 dB SPL the cell is very sharply tuned. Figure 2 illustrates the response of a cell with a CF of 23 kHz.

The interpretation of our results rests largely on the relative importance of the d.c. receptor potential (summing potential) and cochlear microphonic in exciting the afferent nerve fibres. At AP threshold the receptor potential can be as large as 1.6 mV and increases with the level of stimulation to a maximum of about 17 mV, 70 dB above threshold. These recorded potentials are larger than receptor potentials recorded in hair cells in other organs^{7,8} and compare in magnitude with presynaptic potentials recorded elsewhere in the nervous systems⁹. Thus, in view

Fig. 3 Isoamplitude curves of intracellular receptor potentials from experiment 105. *A*, Amplitude of receptor potential in mV.

of their size, it may be that the d.c. receptor potential is responsible for exciting the auditory nerve. If this is so, then the tuning properties of the auditory nerve depend upon the tuning properties of the receptor potential.

To determine whether the frequency response of the intracellular receptor potential corresponds to that of auditory nerve fibres, the receptor potential data must be converted into isoamplitude curves since neural tuning curves are plots of threshold against frequency (isorate). Isoamplitude plots of receptor potential against frequency converted into isoamplitude curves since neural tuning curves are level dependent and, therefore, a comparison with neural tuning curves must be made at a receptor potential that corresponds to the neural threshold. Since AP threshold (which corresponds to single fibre threshold) was 10 dB below the lowest SPL at which receptor potentials were measured, the lowest isoamplitude plot (2.7 mV) is considered to be the closest to the neural threshold tuning curve.

The sharpness of auditory nerve tuning curves is measured in terms of the Q_{10dB} (CF divided by the bandwidth 10 dB above the threshold at CF) and this reaches a maximum of about 10 in the most sensitive fibres³. The Q_{10dB} of the 2.7 mV isoamplitude curve is 9.2 and we therefore conclude that intracellularly recorded receptor potential is tuned as sharply as the auditory nerve and hence that any sharpening of the frequency response beyond that of the basilar membrane mechanics does not involve neural interaction.

We thank Professor R. J. Andrew and Dr K. Bosher for their encouragement and loan of equipment. We thank Drs T. S. Collett and M. F. Land for reading the manuscript and Miss Wendy Randall for technical assistance. This work was supported by the MRC and by an equipment grant from the charities panel of the Readers' Digest.

Lysogeny by f2 phage?

Two prominent properties of lysogenic bacteria are, first, inheritable potentiality for phage production and, second, immunity against homologous phage. Both characteristics are unaffected by growth in the presence of phage anti-serum or by serial subcultures of single colonies. This indicates that every lysogenic cell carries the genetic information for the biosynthesis of a given type of the phage particle¹; so far, however, this has been known only for some DNA bacteriophages. I present here the first demonstration that bacteria can also contain the genetic information for the production of an RNA phage. If *Escherichia coli* bacteria are grown and infected with f2 RNA phage in liquid medium supplemented with guanidinium chloride, many cells subsequently behave as true lysogens. They are 'immune' to f2 and spontaneously release phage identical in morphology, plaque type, serological property, male specificity and single-stranded RNA genome, to the phage used for the initial infection.

f2 is a very small virulent phage and is male specific—

adsorbing only to F pili of male *E. coli* strains. Its single-stranded RNA chromosome has two functions: it is the infectious part of the phage particle, and acts as viral messenger in the infected cell that controls the synthesis of two structural proteins and RNA replicase². This dual function for viral single-stranded RNA is also found in animal poliovirus. Guanidine prevents the synthesis of viral RNA by guanidine-sensitive strains of poliovirus by inhibiting completely the replication of viral genome³. Whether guanidinium chloride has a similar effect in bacteria, that is, inhibition of replication of f2 RNA, is not known.

Guanidinium chloride at a final concentration of 10 mM in Tryptone liquid medium⁴, does not interfere with growth and colony forming ability of *E. coli* bacteria. But when bacteria grown in the presence of guanidinium chloride were infected by f2 in otherwise optimal conditions for f2 growth⁴ the yield of phage was strongly reduced and the percentage of bacteria surviving was markedly increased (Table 1).

To distinguish between resistance and immunity, the guanidinium chloride-treated and f2 infected (multiplicity of infection < 1) male bacteria were allowed to grow with aeration for 3 h after the infection and plated on G-agar (agar⁴ supplemented with 10 mM guanidinium chloride) with anti-phage serum. The colonies thus obtained were picked out, and, when plated on G-agar with the indicator bacteria in the top agar⁴, some of them (about 16%) gave rise to plaques. It is possible that the serum did not inactivate all the phage attached to the F pili. To check this, aliquots of f2-producing bacteria were inoculated into liquid G-medium supplemented with anti-phage serum (at the concentration that inactivated more than 99% of the

Fig. 1 Spontaneous release of the phage by *E. coli*(con. f2) cells. F⁻(con. f2) bacteria were grown overnight in G-medium supplemented with anti-phage serum at the concentration that inactivates more than 99% phage during 5 min. After two washings by centrifugation in saline-calcium and treatment with phage antiserum⁴, the bacteria were inoculated into fresh G-medium (zero time) and incubated with aeration up to the stationary phase of growth. The number of viable bacteria (Δ) and of infective units (○) were estimated hourly (as described in Table 1). Essentially the same results were obtained with male(con. f2) bacteria.

Table 1 Immunity of (*con. f2*) bacteria to f2 phage

Bacterial culture	³ H-leucine-labelled phage ³ H- sedimented with		³ H-uridine-labelled phage ³ H- sedimented with		f2 yield per ml of infected culture	Bacteria surviving infection (%)
	Antiserum (%)	Bacteria (%)	Antiserum (%)	Bacteria (%)		
Hfr RA-2	86	5	14	77	7.8×10^{11}	26
Hfr RA-2, G-medium	82	8	11	75	6.1×10^9	84
Hfr RA-2(<i>con. f2</i>)	84	7	13	78	1.3×10^6	91

To label phage RNA, ³H-uridine (specific activity 7.4 Ci mmol⁻¹, Radiochemical Centre, Amersham) was added to bacterial culture 30 min before infection, at 2.5 µCi ml⁻¹; to label phage coat, ³H-leucine (150 mCi mmol⁻¹, Radiochemical Centre) was added to bacterial culture 30 min before infection, at 2.5 µCi ml⁻¹. Phage stocks were prepared¹ and purified by density gradient centrifugation in CsCl. The phage labelled in its RNA or protein were used separately, at a multiplicity of 0.8, to infect *E. coli* Hfr RA-2 (from Dr K. B. Low), growing either in Tryptone medium or in Tryptone medium supplemented with 10 mM guanidinium chloride (G-medium), and *E. coli* Hfr RA-2(*con. f2*) growing in G-medium at 37 °C (using experimental procedure for f2 growth¹). 10 min after the infection, free phage (that is, phage still attached to F pili, phage ghosts and truly free phage) were removed by violent agitation in a Towers shaker for 3 min. Thereafter the infected bacteria were freed from free phage by two washings of the cells by centrifugation in saline-calcium⁴ and sedimented by centrifugation at 3000 r.p.m. for 5 min (Sorval centrifuge, rotor SS34). Free phage (in the supernatant) were treated with f2 antiserum for 10 min at 37 °C and sedimented at 10,000 r.p.m. for 30 min. The pellet of infected cells was resuspended into fresh medium (Tryptone or G-medium) and that of free phage into saline-calcium. One aliquot of the bacterial suspension was used for the estimation of radioactivity⁵ (in Table 1: ³H sedimented with bacteria), and other for the examination of bacterial survival⁶ and phage production by one cycle of growth¹, using Hfr RA-2 as an indicator strain. Free phage were used for the estimation of radioactivity⁵ (in Table 1: ³H sedimented with antiserum). The results represent average values from three separate experiments. Essentially the same results were obtained with other male bacteria: *E. coli* F⁺CR 63 from Dr M. Radman, and *E. coli* F⁺ts lac⁺ pro⁺/lac⁻ pro⁻ from Dr D. J. Cummings (the latter grown at 30 °C). f2 phage was donated by Dr A. D. Kaiser.

phage during 5 min), grown to stationary phase and then plated again with antiserum. After five successive re-isolations (after long growth with anti-phage serum in each case) bacteria showing completely new characteristics were isolated: (1) they were not resistant to f2, but did not produce the phage when infected, as though they had been 'immune' to f2 (Table 1) and (2), during the growth in the liquid medium they released phage (Fig. 1). These bacteria are designated (*con. f2*), that is, containing the genetic information for f2 biosynthesis.

It is unlikely that anti-phage serum treatment did not remove all the phage and that some phage still remained

adsorbed to F pili of male bacteria. If this were to occur, however, it would not explain the 'immunity' observed. Definite proof that the phenomenon described here is not due to f2 particles adsorbed to F pili was obtained by constructing F⁻(*con. f2*) bacteria using F⁺ts (temperature sensitive) cells for infection. At the inhibitory temperature, the thermosensitive F⁺ plasmid is diluted out from the *E. coli* population, because its replication is inhibited and it is inherited unilinearly by the descendants of the original F⁺ bacteria⁷. One aliquot of *E. coli* F⁺ts lac⁺ pro⁺/lac⁻ pro⁻ cells was allowed to grow in G-medium at 42 °C, while the other was infected in the same medium at 30 °C with f2, and after 10 min warmed to 42 °C by adding fresh medium prewarmed at 60 °C. The growth of cells was continued at 42 °C for 3 h, and infected and non-infected bacteria were plated at 42 °C on MacConkey agar—enabling us to distinguish male from female bacteria⁸. Colonies of female cells were picked out and F⁻(*con. f2*) bacteria were made as above for (*con. f2*) male cells; the only difference was that bacteria were grown at 42 °C. Controls on MacConkey agar were used at each step of F⁻ and F⁻(*con. f2*) strain isolation. The female cells thus obtained were lac⁻ pro⁻, and they could not adsorb male-specific phage f2, R17 and MS2. F⁻(*con. f2*) bacteria, however, produce phage spontaneously (Fig. 1). This phage is, by its morphology (Fig. 2), male specificity, serological property, single-stranded RNA genome (examined by the method of Bradley⁹) and plaque type (on Tryptone agar), identical to the phage f2. But on G-Tryptone agar mottled plaques occur, from the turbid zone of which male (*con. f2*) bacteria can be isolated. The functional state and the location of genetic information for phage production in (*con. f2*) bacteria, and the molecular mechanism of guanidinium chloride action are under investigation.

I thank Drs A. D. Kaiser and D. J. Cummings for discussions, Dr Durda Novak for antiserum preparation, Dr Mercedes Wrischer for electron micrographs, and Miss Josipa Hrženjak for technical assistance.

Ether induced morphological alteration of Pf-1 filamentous phage

BACTERIOPHAGES of filamentous structure have been isolated in several species of bacteria and all have similar physico-chemical properties¹. They consist of single-stranded circular DNA and two species of proteins—A protein and B protein. They are released from infected cells without disintegrating the cells and are inactivated on exposure to chloroform although the presence of lipids in the virion has not been reported. During a study of Pf-1, a filamentous phage which propagated on strain K of *Pseudomonas aeruginosa*², we found that it is almost completely inactivated with ether, whereas phage fd and Xf are refractory to it. Ether sensitivity of the viruses is generally thought to be an indication of the presence of lipids in the virion. Pf-1 might, therefore, be thought to contain lipids in its structure. We report here a study of the inactivation and morphological alteration of Pf-1 induced by ether and the results of chemical analysis of Pf-1 which suggest the absence of lipids in this virus.

For the propagation of Pf-1 and fd, nutrient broth was used and Xf was propagated in the medium described by Kuo *et al.*³. The effects of organic solvents on the plaque forming activity of filamentous phages are shown in Table 1. Pf-1 was completely inactivated by ether and other solvents tested, whereas fd and Xf were only inactivated with chloroform.

Table 1 Inactivation of filamentous phages by organic solvents

Treatment	Pf-1	Titre (PFU ml ⁻¹)		
		Xf	fd	
None	1.3×10^{11}	1.6×10^{11}	4.2×10^{11}	
Ethyl ether	$< 10^3$	1.5×10^{11}	3.6×10^{11}	
Chloroform	$< 10^3$	8.0×10^7	1.5×10^7	
Methanol	$< 10^3$	NT*	4.2×10^{11}	
Acetone	$< 10^3$	NT	3.0×10^{11}	

Culture fluid containing about 10^{11} PFU ml⁻¹ phage was mixed with an equal volume of solvent. The mixture was stirred gently with a pipette and allowed to stand for 10 min at room temperature. Phage activity in the aqueous phase of the mixture separated by low-speed centrifugation (500g, 5 min) was titrated using a plaque technique.

*NT, Not tested.

Electron microscopic observation of ether treated Pf-1 showed that phage filaments disappeared and many rod-like structure appeared (Fig. 1a). This morphological change observed in Pf-1 could be the reason for the loss of the activity of this phage. The width of the rod was 185 Å and the length was variable but always shorter than that of the phage filament. The middle portion of the rod was densely stained with phosphotungstate. From these electron microscopic images two types of structure for the rod can be postulated. One is a hairpin like structure which can be formed by joining two phage filaments bent like a hairpin, and the other is a hollow cylinder formed by the swelling of a phage filament. Shadowing techniques revealed the surfaces of the rod-like structures, and the grooves which would be expected from the images of hairpin like structures were not observed (Fig. 1b). The effects of ether on the activity of Pf-1 were rapid, and after exposure to the ether vapour for even a few seconds a decrease of its activity could be measured. Electron microscopic observation of this preparation showed that phage filaments were swelling into rod-like structures at a portion of a

filament. Penetration of the stain occurred on some of them, giving the appearance of the rod-like structures seen in Fig. 1a (Fig. 1c). These results suggest that ether treatment causes swelling of the phage into a hollow cylindrical structure.

To investigate the chemical composition of Pf-1, phage was purified from infected culture fluid with the method of ammonium sulphate fractionation and equilibrium density gradient centrifugation of CsCl. Bacteria were removed from 2 l of fluid by centrifugation (8,500g for 30 min), 240 g of ammonium sulphate was added gradually with stirring to precipitate the phage.

The precipitate was collected by centrifugation (8,500g, 30 min) and dialysed against 0.01 M Tris-HCl buffer pH 7.4 overnight. The cell debris that remained in the phage

Fig. 1 Electron micrographs of Pf-1 treated with ether. *a*, Negatively stained Pf-1 treated with ether. The purified phage was mixed with an equal volume of ether for 10 min at room temperature. The aqueous phase was negatively stained with potassium phosphotungstate, pH 7.2, on the electron microscopic grid prepared as described by Fukami and Adachi⁸. Scale bar represents 100 nm. *b*, The same preparation of Pf-1 as in (*a*) was shadowed with tungstate at an angle of 30° using an Edwards E306 vacuum evaporator equipped with an electron beam device. *c*, Negatively stained Pf-1 treated with ether vapour. Purified phage was placed on specimen grids and exposed to ether vapour for 5 s by keeping the grids above the test tube containing ether.

suspension was removed by three cycles of differential centrifugation (20,000g, 10 min and 100,000g, 2 h). The gradient consisting of three steps (1.4, 1.3 and 1.2) and spun at 84,000g for 4 h. The phage band which appeared in the lower third of the gradient was collected, dialysed against 0.01 M Tris-HCl buffer overnight and further purified by CsCl equilibrium sedimentation (115,000g, 21 h). The phage band at 1.29 density was collected and dialysed against the buffer and this is referred to as the purified phage preparation. This phage preparation contained 1.6×10^{13} PFU per ml (plaque forming units) of phage which was 20% of the activity detected in the infected culture fluid. To demonstrate the purity of the phage preparation it was subjected to polyacrylamide gel electrophoresis containing sodium dodecyl sulphate (SDS) to separate the proteins following the method of Dunker and Rueckert⁴.

Fig. 2 Thin-layer chromatography of the lipids fraction extracted from Pf-1. Lipids were extracted from the purified phage suspension or bacterial cells by the method of Braunstein and Franklin⁵. Purified phage (1×10^{13} PFU) or bacterial cells (2×10^{10} cells) were suspended in 4.8 ml of 0.01 M Tris-HCl buffer, pH 7.4. Methanol-chloroform (2:1, v/v, 18 ml) was added to the suspension and intermittently shaken for 2 h at room temperature. The precipitated residue was centrifuged at 3,000g for 20 min and the supernatant retained. Extractions were repeated in the residue. Chloroform (6 ml) was added to the supernatant and mixed. Then 6 ml of water was added and also mixed. The emulsion was centrifuged at 3,000g for 30 min and the chloroform layer was collected, dried in room temperature and retained as the lipid fraction. Lipid extracts dissolved in the mixture of chloroform and methanol were applied 2 cm from one edge of a chromatographic plate. The plate was placed in a cylindrical jar containing 10 ml of chloroform-methanol-water (65:25:4, v/v) and allowed to stand until the front of the solvent reached 11 cm from the edge of the plate. The plate was air-dried and then transferred to the other jar containing 10 ml of the mixture of *n*-hexane-ethyl ether-acetic acid (90:10:1, v/v) and developed further until the solvent front reached 19 cm from the edge of the plate. The spots of lipid were visualised by staining with iodine or molibden blue. *a*, Lipid extracts from strain k of *Ps. aeruginosa*; *b*, lipid extracts from Pf-1; *c*, solvent alone; *d*, standard lipids, from top to bottom; triolein, diolein, cholesterol and oleic acid.

Only the two visible bands of protein which represented A protein and B protein respectively were stained. No other bands indicating the contamination of the proteins from bacteria were detected.

Lipid was extracted from the purified Pf-1 by the method of Braunstein and Franklin⁵ using 2.5 mg of phage (1×10^{13} PFU). Lipid fractions were analysed on a thin layer chromatography plate coated with silica gel 60 (Merck). Using the same plate the lipid fractions extracted from host bacteria (2×10^{10} cell) were analysed simultaneously. The plate was initially developed with a solvent mixture consisting of chloroform-methanol-water (65:25:4, v/v) and then with *n*-hexane-ethyl ether-acetic acid (90:10:1, v/v). The plate was stained with iodine or molibden blue; several spots were visualised on the specimens extracted from bacteria but none on the extracts from Pf-1. This implied that Pf-1, although it is sensitive to ether, does not contain significant amounts of lipid in its structure. Significant levels of lipids have been found in many other ether-sensitive viruses.

In lipid-containing viruses the morphological alterations induced by ether-treatment are thought to be caused by the extraction of the lipids which have a role in maintaining the morphological integrity of the virion. In Pf-1, the morphological alteration seems not to be the disintegration of the phage filament but its swelling into a hollow cylinder.

The structure of filamentous phages including Pf-1 has been extensively examined by X-ray diffraction and chemical analysis. A structural model has been presented by Marvin⁶.

The protein shell of the filamentous phage is constructed from coat protein molecules exhibiting largely an α -helix structure and extending in an axial direction with the phage filaments overlapping each other like fish scales to form a hollow cylindrical tube, in which the virus DNA is wrapped. In the phage protein shell, the coat protein molecules were held together by the hydrophobic bond created by the hydrophobic region of the coat protein molecules⁷. It is assumed that ether probably disrupts these bonds and induces deformation of the arrangement of the coat proteins on the protein shell and results in the swelling of phage filament. Our preliminary experiment to observe the DNA molecules in ether-treated phage specimens by the technique of protein monolayer method revealed the presence of many small circular DNA molecules similar in size and shape to those extracted by the phenol method from the purified Pf-1. This suggests that the DNA molecules packed in the protein shell might be released concomitantly with the swelling of the phage filament.

Aflatoxin B₁-oxide generated by chemical or enzymic oxidation of aflatoxin B₁ causes guanine substitution in nucleic acids

AFLATOXIN B₁ (AFB₁) has the highest biological activity of the four naturally occurring aflatoxins produced by the

mould *Aspergillus flavus*¹. Feeding studies have shown it to be the most potent liver carcinogen known for the rat². Its ingestion by man is associated with the high primary liver cancer incidence in certain parts of Africa³. There is much evidence to suggest that AFB₁ requires metabolism to exert both its carcinogenic and mutagenic effects (reviewed in ref. 4). Structure-activity⁵, as well as chemical studies^{6,7} indicate that the major route for activation proceeds through mixed function oxidase attack yielding the 8,9-oxide (previously called the 2,3-oxide but renumbered according to IUPAC recommendations). Attempts to chemically synthesise this metabolite have so far been unsuccessful. We report here that peracid oxidation of AFB₁ generates AFB₁-8,9-oxide, and that this latter compound reacts readily with nucleic acids to give adducts identical to those obtained after liver mixed function oxidase (MFO) activation *in vitro* and *in vivo*.

Using a modification of a chemical procedure recommended for the epoxidation of acid sensitive olefins⁸, we are able to covalently bind AFB₁ to DNA, polyguanylic acid or deoxyguanosine. Enzymic binding to nucleic acid was achieved by incubating the carcinogen with rat or hamster liver post-mitochondrial supernatants and DNA together with the necessary cofactors.

Figure 1 shows the chromatographic profile on Sephadex LH-20 of deoxynucleosides obtained by enzymic hydrolysis of DNA after MFO activation of AFB₁ compared with that after chemical activation. Four peaks of radioactivity were obtained, in each case the major peak being product I. Freeze-drying of fractions from peaks I and II and injection onto a silica reversed-phase column and subsequent high pressure liquid chromatography showed each peak to be

homogeneous (data to be presented elsewhere).

Mild acid hydrolysis of AFB₁-reacted DNA, after MFO activation, to release purine bases and subsequent LH-20 chromatography of the hydrolysate, showed three peaks of radioactivity. Two of the peaks had similar retention times to the minor peaks (III and IV) obtained after enzymic hydrolysis. A similar chromatographic profile after mild acid hydrolysis was obtained for AFB₁-reacted DNA after chemical activation (data not shown).

Evidence for the structures of the various products of AFB₁ reaction with DNA was obtained by substituting deoxyguanosine or polyguanylic acid as nucleophiles, in place of DNA, in the chemical oxidation system. Chromatography of the deoxyguanosine reaction products on Sephadex LH-20 gave peaks of radioactivity coincident with peaks I, II and IV obtained in enzymic hydrolysis of DNA after either chemical or enzymic reaction with AFB₁ (Fig. 2). Incubation of the deoxyguanosine reaction products at pH 9.0 for 24 h and subsequent Sephadex LH-20 chromatography showed peaks II and IV to largely disappear and be replaced by peaks I and III. Strong acid hydrolysis (1 N HCl, for 60 min at 100 °C) of AFB₁-reacted polyguanylic acid from a chemical activation experiment and Sephadex LH-20 chromatography of the reaction products showed two major peaks of radioactivity (III and V) and a minor one (IV).

Thus, all the reaction products obtained after neutral enzymic hydrolysis of DNA, except for V, seem to be derived from guanine. Peak V is that of AFB₁-8,9-dihydrodiol, since it is excluded at the fifth void volume on Sephadex LH-20 chromatography⁹, and co-chromatographs with synthetically prepared diol. Acid hydrolysis of DNA

Fig. 1 Chromatographic profiles of neutral enzymic digests of DNA on Sephadex LH-20. —, ¹⁴C radioactivity; ---, A₂₆₀. *a*, Enzymic activation of AFB₁. Hamster or rat liver post-mitochondrial supernatant (1 ml of a 25% homogenate in 150 mM KCl, equivalent to 250 mg of fresh liver) was incubated in 100 mM sodium phosphate buffer pH 7.4 containing 1.5 μmol NADP⁺, 20 μmol glucose-6-phosphate, 25 μmol MgCl₂, 10 mg of calf thymus DNA and 200 μg ¹⁴C-AFB₁ dissolved in 0.2 ml dimethyl sulphoxide (specific radioactivity 0.52 mCi mmol⁻¹) in a total volume of 3 ml. After incubation at 37 °C for 60 min, the incubation mixture was extracted once with an equal volume of phenol-cresol, the nucleic acid precipitated from the aqueous layer with ethoxyethanol and redissolved in 5 ml sodium chloride-sodium acetate buffer. Contaminating RNA was removed by incubation with ribonuclease-A (50 μg ml⁻¹) and the DNA re-extracted with 0.5 volumes phenol-cresol. The nucleic acid was then precipitated, redissolved and chloroform extracted three times before centrifugation at 100,000g for 60 min to remove glycogen. 1.7 mg AFB₁-reacted DNA dissolved in 1 ml 0.3 M sodium chloride-0.25 M sodium acetate-0.015 M magnesium acetate was digested with 100 μg deoxyribonuclease I for 60 min at 37 °C. After the addition of 3 units bacterial alkaline phosphatase and 0.05 units snake venom phosphodiesterase the mixture was incubated for a further 18 h at pH 7.0 and 37 °C. *b*, Chemical oxidation of AFB₁. 10 mg of calf thymus DNA were dissolved in 8 ml 20 mM sodium phosphate buffer pH 7.4 and added to a solution containing ¹⁴C-AFB₁, dissolved in 8 ml dichloromethane (67.5 μg ml⁻¹ ¹⁴C-AFB₁, specific radioactivity 0.4 mCi mmol⁻¹ prepared as previously described¹¹). To this two-phase system was added 625 μg 3-chloroperbenzoic acid (4 molar excess) and the whole stirred for 25 h at room temperature in the dark in a stoppered flask. At the end of this time, the two phases were separated, and the aqueous phase, containing the nucleic acid, extracted five times with equal volumes of chloroform. The nucleic acid was then precipitated in three volumes of ethanol and redissolved in 20 mM Tris HCl pH 7.0. This ethanol precipitation step was repeated three times and the nucleic acid finally redissolved in 0.3 M sodium chloride/0.25 M sodium acetate. 4 mg of the AFB₁-reacted DNA dissolved in 1 ml sodium chloride-sodium acetate-magnesium acetate were digested using twice the enzyme concentrations in (*a*). Enzyme digests were chromatographed on Sephadex LH-20 columns (110 × 1.75 cm) eluted with water, 4-ml fractions collected and an aliquot counted for radioactivity. Absorbance was measured at 260 nm. The main ultraviolet absorbing peaks from left to right are deoxycytosine and thymidine combined, deoxyguanosine and deoxyadenosine. The results are from two similar columns run separately.

or poly G to which AFB₁ has been bound, leads to release of this derivative, showing that AFB₁-8,9-oxide is formed by either enzymic or chemical oxidation of AFB₁.

3-Chloroperbenzoic acid is a highly specific oxidising agent for the epoxidation of olefinic double bonds. Use of this reagent to epoxidise AFB₁ in the presence of DNA, results in a high percentage of nucleic acid bases being modified. No evidence was obtained for direct action of the peracid on DNA. In the conditions outlined here, one molecule of AFB₁ is bound per 100 molecules of base, thus, approximately one in every 20 guanine bases are modified. Increasing the amount of AFB₁ with a proportionate increase in the concentration of peracids leads to a higher level of binding. With liver MFO, lower amounts of binding were found but this was again dependent on the AFB₁ concentration.

Neutral enzymic hydrolysis of DNA leads to the release of deoxynucleoside adducts⁹, whereas mild acid hydrolysis results in the release of base adducts¹⁰. Peaks I and II seem therefore to be deoxyguanosine adducts of AFB₁-8,9-oxide whereas III and IV are guanine adducts of the epoxide. Mild acid hydrolysis (0.1 N HCl at 70 °C for 20 min) of peak I converts it to peak III (data not shown) suggesting

Fig. 2 Chromatographic profile of deoxyguanosine AFB₁-reacted adducts after chemical oxidation of AFB₁ at pH 7.4. —, ¹⁴C radioactivity; ---, A₂₈₀. Deoxyguanosine was reacted with AFB₁ as in Fig. 1b, with the exception of the ethanol precipitation step. Chromatography on Sephadex LH-20 was as in Fig. 1.

that peak III results from the loss of a sugar residue from peak I. Incubation of peak II at 37 °C, pH 9.0 converts it to peak I while peak IV is converted to III. Two explanations for this are that (1) alkali attacks the base-AFB₁ adduct to open the lactone ring, or (2) alkali attacks the adduct to open the imidazole ring of guanine. Explanation (1) is unlikely since peak I has the characteristic ultraviolet absorption maximum of AFB₁ between 360 and 370 nm and also incubation of AFB₁ at pH 9.0 does not result in lactone ring opening. Explanation (2) is substantiated by the absorption spectrum of peak I at pH 7.0 in the range 260–280 nm which is characteristic of a pyrimidine, suggesting destruction of the imidazole ring of the purine moiety.

Imidazole ring opening of guanine in mild alkaline conditions is characteristic of N-7 substituted guanines¹¹. Hydrolysis of AFB₁-reacted-DNA at neutrality for 30 min at 100 °C, results in the removal of the AFB₁-guanine adduct. Chromatography of the heat-hydrolysed supernatant after acid precipitation of the pyrimidine oligonucleotides at 0 °C on Sephadex LH-20 shows peaks III and

Fig. 3 Postulated structures of products I and II.

IV have been released (data not shown). Again this is a characteristic of guanine alkylated at the N-7 position¹².

Reaction at other positions in guanine is ruled out by (1) the relative ease of imidazole ring opening, (2) depurination at 100 °C in neutral conditions, (3) the ease of release of AFB₁-8,9-dihydrodiol from the nucleoside-AFB₁ adducts in mild acid conditions and (4) the base-AFB₁ adducts are stable at 100 °C in 1 N HCl. These findings lead us to assign the structures in Fig. 3 to the various products formed on reaction of AFB₁-8,9-oxide with DNA. Peaks I and II are the deoxyguanosine adducts whereas peaks III and IV are the guanine adducts. Data to be presented elsewhere shows, in agreement with other workers that products I to V are also formed on hydrolysis of liver DNA after ¹⁴C-aflatoxin B₁ administration to rats. Work is in progress to obtain sufficient of the products for chemical characterisation as well as identifying any possible minor reaction products.

The results reported here indicate that AFB₁-8,9-oxide is formed during peracid oxidation or MFO activation of AFB₁ and that this metabolite reacts with nucleic acid. Two major products of reaction are found, as has also been shown by Swenson *et al.*¹³, and these are both derived from guanine, almost certainly through N-7 substitution.

Covalent binding of AFB₁ with guanine at the N-7 position is likely to induce frame-shift mutations due to intercalation of the AFB₁ molecule together with base-substitution mutations as a result of misrepair. This reaction may therefore be important in the initiation of cancer as well as mutation induction in microorganisms by this potent mycotoxin.

matters arising

Repression of synaptic efficacy in frog skeletal muscle

GRINNELL, Rheuben and Letinsky¹ show convincingly that when the transplanted frog sartorius muscle is innervated by two foreign nerves, control of the muscle fibres may be shared between the two, one nerve being effective at transmission the other eliciting only subthreshold junction potentials of low quantal content. They suggest this depends on a mutual competition between nerves similar to that invoked to explain selective reinnervation of urodele muscle^{2,3}.

I wonder whether this pattern of innervation is simply a property of the frog sartorius muscle. Luff and Proske⁴ have found using tension measurements, that there is very little overlap between motor units when they measure twitch tension but extensive overlap (50% or more) when tetani were used. Furthermore, motor units in which the twitch tension fluctuated from trial to trial required high rates of stimulation to achieve peak tetanic tension and had low twitch tetanus ratios. This suggests that normally many muscle fibres are supplied with junctions which have a low safety factor for neuromuscular transmission. Presumably those fibres are also supplied with a safe junction from another motoneurone. Since there are only about 12 motor axons supplying the sartorius it seems unlikely, although not impossible, that the reduced efficacy of some of the junctions depends on an embryological matching process such as that postulated to account for selective innervation of muscles after nerve regeneration in urodeles. Rather it may be because sartorius muscle fibres tend to maintain one neuromuscular junction at high efficacy and reduce the efficacy of others on the same fibre, regardless of the embryological origin of the synapses, an interesting developmental mechanism in its own right but not necessarily related to the formation of specific connections. One could answer the question by finding out whether in the preparation used by Grinnell *et al.* there were unequal connections made by different motoneurons within the two populations of foreign nerve fibres. The test would be to split one of the foreign nerves and see if there was evidence for competition between different populations of fibres in one nerve, as there is between

the populations of fibres of the two foreign nerves.

⁴ Luff, A. R. & Proske, U. J. *Physiol. Lond.* 258, 673–685 (1976).

GRINNELL *et al.* REPLY—Mark rightly asks the question: If competition between two different nerves reduces the effectiveness of many terminals, as we report, then should not the same phenomenon occur between axons of the same nerve? If so, might this not be a normal phenomenon whereby each fibre acquires (relatively) exclusive innervation by one axon? This was an obvious question to us as well, and we have done some experiments of the type he suggests.

Our results indicate that there is competition between axons of the same nerve, but much less than between axons of two different foreign nerves. When a single nerve (normal or reinnervated) is split into two or more segments, with one to three functional motor units in each, there is little if any twitch overlap (usually 5% or less), but up to 25% tetanus overlap. This implies the existence, in *Rana catesbeiana* as in *Litoria aurea*¹, of some subthreshold polyneuronal innervation, and leads us to agree with Mark that the competition we have demonstrated between pairs of foreign nerves may be a special case of similar competition between axons of a single nerve. In our experiments there is a sharp quantitative difference between competition in the two cases, however, and probably a qualitative difference. The tension overlap we find between axons in singly innervated muscles does not approach that reported by Luff and Proske⁴. The explanation for this difference may be one of species or technique. It is noteworthy, for example, that Luff and Proske's Ringer apparently contained only 1.08 mM Ca^{2+} compared with the 1.8 mM in our amphibian Ringer and that used by most other investigators. In four experiments in our laboratory, shifting a normal sartorius preparation from 1.8 mM Ca^{2+} to 1.08 mM Ca^{2+} Ringer caused no change in 50 per cent tetanus tension, but a reversible 53±

28% drop in twitch tension, suggesting that quantal content in a high proportion of junctions can be reduced below threshold by that reduction in Ca^{2+} concentration. This could also help account for Luff and Proske's low twitch-tetanus ratios. Although we find a few subthreshold junctions in singly reinnervated muscles, normally the quantal content is close to threshold, never as low as is commonly found in doubly innervated muscles (under 10). Moreover, the average twitch tension developed by simultaneous stimulation of both of two foreign nerves is conspicuously less (in percentage of fibres twitching) than that elicited by stimulation of the nerve in singly reinnervated muscles. This implies either fewer fibres are innervated, or that there is a greater number of subthreshold junctions where two different nerves are present rather than only one. Since we normally find that either nerve when tetanised can drive almost 100% of the muscle, most of the junctions formed by each must be subthreshold².

The competition we describe between the foreign somatic motor nerves is nonspecific; neither has an apparent innate advantage. Thus we do not propose this as a direct explanation for the reported instances of specific repression of one nerve by another. On the other hand, we do see some distinction between axons of two different nerves, compared with those of a single nerve. Moreover, the competition occurs in a muscle with focal rather than distributed endings, and hence is amenable to direct study of single 'repressed' endings. It is our hope that an understanding of this interaction may provide important insights into more specific forms of interaction.

reviews

Jumping into black holes

Roman Znajek

The Iron Sun: Crossing the Universe Through Black Holes. By Adrian Berry. Pp. 176. (Jonathan Cape: London, 1977.) £3.95.

ADRIAN BERRY has written a book about making black holes and jumping into them. He claims that the latter is a way of achieving instantaneous interstellar transport. After reading half the book one eventually discovers that it is called *The Iron Sun* because Berry proposes to build the holes by using magnetic fields to sweep together bits of iron (and other junk) that float around between stars. As the holes are to be ten times as massive as the Sun, and are to be situated at the 'safe' distance of one light year, this is clearly going to be a colossal task. Berry, however, thinks that humanity will continue to increase its economic output at an average annual rate of 3 per cent, and will therefore be able to achieve this feat "within about 250 years' time". Opposition is to be expected from assorted politicians, conservationists and second-rate scientists, but Berry is nevertheless confident that the project will be successfully completed by a conspiracy of dedicated technocrats.

I should explain that a black hole is a region of space where gravity is so strong that nothing, not even light, can escape. Its formation is inevitable when a sufficiently compressed piece of matter gets too cold to support itself against its own gravitational field. A ten solar mass lump of iron will certainly start to collapse under its own weight. What Berry does not seem to realise is that it will also get very hot. It is possible that the outer regions will stop collapsing and then get blown away. In other words, Berry may have created a recipe for an artificial supernova. A supernova one light year away would be a thoroughly unpleasant object and the conservationists would be justified in opposing it. There is of course no point in building the hole much further away because it is precisely in order to travel across such distances that the hole is being built in the first place.

An optimist may say that this is a mere technical difficulty and that there might be some way of cooling the matter as it collapsed. So how is a black hole going to help us get to the

stars? According to Berry, whenever a black hole is formed, a white hole 'simultaneously' appears in another part of the Universe. (A white hole is the opposite of a black hole: instead of falling into it, matter tends to fall out.) The two holes are supposed to be connected by a short piece of space that is 'outside' normal space—a kind of cosmic Suez Canal. A properly navigated spaceship can disappear into the black hole and reappear an instant later coming out of the white hole, even though a beam of light would take many years over the same journey in ordinary space.

Berry admits that many problems must be solved before such a voyage is possible. He confesses at the end of the book that no one knows where the white hole is going to appear. The fact is that no one knows *why* the white hole is going to appear. The idea that black holes are linked to white holes is a speculation which very few relativists have taken seriously. Speculation is legitimate, but quoting it as established knowledge is not. Berry has performed a grave disservice to science by not passing on warnings like: "concepts outside our present knowledge of physics must be invoked" which regu-

larly appear in the references he relies on. He owns up to the instability of the short cuts through which his spaceships travel, but does not draw the appropriate conclusion that the short cuts simply don't exist.

There are very many errors in this book. Perhaps the worst is Berry's claim that absolute time exists in the theory of special relativity. He says that although "many people who should know better" deny it, Einstein himself believed in absolute time and the simultaneity of events. This is an important issue for Berry, because if absolute time did not exist his instantaneous form of transport would lead to logical paradoxes. Unfortunately, the page to which Berry refers in Einstein's *The Meaning of Relativity* appears to be about something else, and if Berry looks at the preceding page he will no doubt decide that Einstein too needs to know better . . .

Adrian Berry should have known better than to write this book. □

Immunopathology

Textbook of Immunopathology. Second Edition. Vol. 1: Pp. xlviii+1-554. Vol. 2: Pp. xlviii+555-1,118. Edited by P. A. Miescher and H. J. Muller-Eberhard. (Grune and Stratton: New York and London, 1976.) \$49.50; £30.20 each volume.

THIS textbook of immunological mechanisms in disease and immunopathology has become a standard work in its field of medicine. It is indispensable to those who are involved in clinical immunology or in the study of animal disease models of immunologically mediated phenomena. A consortium of expertise from both sides of the Atlantic has contributed the 63 chapters contained in this two volume work. The quality of each is uniformly high. The format of the textbook has not been altered from the first edition; obviously the editors have not wished to tamper with success. Almost 400 new pages of text, however, have been

added, thereby expanding the volume by one-third. A final chapter, an appendage, on principles of methods in immunology seems out of place in this book, and is hardly an adequate source of information on methodology for investigators in the field. It is dissonant with the highly authoritative scholarship of the preceding 62 chapters.

Almost 75 years have elapsed since Metchnikoff's publication of lectures on immunopathology. He certainly would be gratified to see how his fundamental insights into immunopathology have blossomed into a complex, vital and growing field of medicine and medical research. I think that he too would have prized this textbook.

Fred S. Rosen is James L. Gamble Professor of Pediatrics at Harvard Medical School and Chief of the Immunology Division, Children's Hospital Medical Center, Boston, Massachusetts.

Behaviourist history

Behaviourism and the Limits of Scientific Method. By Brian D. Mackenzie. Pp. 193 (Routledge and Kegan Paul: London and Henley, 1977.) £4.95.

IN *Behaviourism and the Limits of Scientific Method* Dr Mackenzie traces the history of behaviourism from Watson to Skinner and examines its philosophical assumptions. He notes that there have been several different kinds of behaviourist. Watson's insistence that in order to be a science, psychology should be concerned only with observable behaviour and not with the furniture of the mind was followed by a more general concern with scientific method, and many behaviourists went on to embrace the then fashionable reductionist doctrines of the logical positivists and operationists. The most extreme version of behaviourism is that still being promulgated in increasing isolation by B. F. Skinner, who abjures all theoretical concepts.

Dr Mackenzie makes some interesting points. He claims for example that the learning theorists of the thirties—Hull, Tolman and Guthrie—were led astray by their adherence to logical positivism. Because they believed that their theories were merely ways of systematising the data and that their explanatory concepts had no ontological status, they failed to make explicit many of the assumptions behind their theories: the mutual misunderstandings thus engendered led to many pointless wrangles. It is certainly true that, as they later came to realise, their theories lacked rigour, but the theoretical looseness surely arose less from their philosophical assumptions than from the fact that at that time no formal language existed in which to couch rigorous explanations of behaviour.

Dr Mackenzie fails to note the difference between postulating intervening variables and putting forward a mechanism to explain behaviour. It is ironic that psychologists should have been reluctant to reify their explanatory concepts. It is clear that real processes intervene between the stimulus and the response and these processes are instantiated in a corporeal body known as the brain. To understand the logic of the brain's connectivity, psychologists needed to evolve new concepts, but the reality of the brain cannot be doubted in the same way as it is possible to doubt the reality of quarks.

Although Dr Mackenzie has provided an interesting and original account of the philosophy and history of behav-

ourism, the book has one curious fault: he has kept his eye so firmly on his quarry that he seems unaware that there have always been psychologists of many different colours. He even refers to behaviourism as "the most important single influence in the continuing development of modern psychology". This is a startling assertion to make at a time when many psychologists explicitly take account of introspection, and when almost all are concerned with building process models. Behaviourism has in fact never had much effect on the study of perception, language or cognition,

even those studying memory have shaken off its influence over the past two decades. Moreover, at the time when Hull, Tolman and Guthrie were at their most influential, Lashley, Kohler, Wertheimer and Bartlett were putting forward ideas and theories of a very different kind. Dr Mackenzie clearly did not come to praise behaviourism: it is a pity he has not appreciated that he is too late to bury it.

Photoconductive techniques

Photoconductivity and Related Phenomena. Edited by J. Mort and D. M. Pai. Pp. 502. (Elsevier, Amsterdam and New York, 1976.) Dfl. 155; \$61.95.

PHOTOCONDUCTIVITY is probably the most sensitive of all the electrical phenomena, to the defect properties of insulators and semi-insulators. Furthermore, the photoconductive technique can be studied under a wide range of experimental variables such as wavelength, intensity, temperature, applied electric field, and in steady-state and non-steady conditions. Consequently, photoconductive data are often very distinctive and rich in structure, providing a powerful probe for investigating the trap parameters and structure of solids, as well as an insight into physical processes involved such as absorption photogeneration recombination, transport, intramolecular relaxation, electro-photon interaction, and so on.

It is not surprising, therefore, that in recent years photoconductivity techniques have been increasingly utilised in the study of the disordered and amorphous state. This book describes the applications of photoconductive techniques to these materials, a collection of review articles by leading workers in the field.

The first nine chapters are devoted to basic concepts and experimental techniques. The book opens appropriately with a review of contact effects, often neglected and ignored (conveniently?), yet absolutely fundamental to a proper understanding of photoconductivity. Chapter 2 deals with experimental techniques, with particular attention on transient and time-varying Hall and photo-electromagnetic

techniques. Chapter 3 is concerned with the time-dependent photoconductivity, an area which I believe offers the greatest scope for future study, but which poses formidable problems. Chapters 4–9 deal with photoconductivity in a variety of materials: covalent semiconductors, molecular crystals, amorphous tetrahedrally bonded solids, amorphous chalcogenides, and polymeric photoconductors. The most comprehensive of these, and a very readable account, is the one on amorphous chalcogenide and non-polar liquids. There is surprisingly little duplication considering the closely-related nature of the work, and that the works are by different sets of authors, thus reflecting the wide-ranging versatility of photoconductive techniques.

The final two chapters are concerned with applications of photoconductivity. Chapter 10 deals with photoelectronic semiconductor devices. I would have liked to have seen more space devoted to this chapter, and more emphasis on devices using disordered photoconductors, because this is what the book is really all about; even if this were at the expense of those based on crystalline materials. The last chapter, a fitting close to the book, is concerned with electrophotography, and provides a good account of the basic principles of electrophotography, image formation and development, and requirements for photoreceptor materials.

On the whole, most of the articles are concerned with underlying physical processes stressed rather than the theory, and most are very readable. The book is prepared to a high standard, and should appeal to experts (and others) in the field, although I doubt very much if the price (\$62) will.

Simplifying sociobiology

Sociobiology and Behaviour. By D. P. Barash. (Elsevier Scientific: New York, 1977) Hardback, \$9.95; paperback, \$4.95

Sociobiology and Behaviour is essentially a much abbreviated version of parts of E. O. Wilson's *Sociobiology. The New Synthesis* (Harvard University Press). After introducing the basic ideas of natural selection, Barash proceeds through the by now familiar topics: altruism, living in groups, mate selection, parental investment, and aggression. Although Barash covers the 'right' topics, is usually clear in what he says, and provides plenty of good examples, this is not a book I would recommend to first-year undergraduates, the intended audience.

Although I am all in favour of making scientific texts clear and informal in style, I find Barash's racy prose annoying. Phrases such as "tunnel of love" (sticklebacks nest), "shennanigans of a love-crazed prairie chicken" (lek behaviour), "slice of the sociobiological cake" (meaning uncertain) lack both elegance and precision. This, however, is a purely aesthetic reaction, and my real objections to the book arise from three aspects of its scientific content. First, Barash claims more for sociobiology than it deserves. He proudly proposes (for the first time, he says) the Central Theorem of Sociobiology—"animals should behave so as to maximise their inclusive fitness". It sounds to me rather like what Darwin said more than a hundred years ago. Second, the book sets a bad example to students by giving the wrong impression of what scientific prediction is all about. On p.259 we are told of the prediction of "sociobiologic theory" that "territories will be defended when it is adaptive for individuals to do so, i.e. when their personal inclusive fitness (*sic*) is maximised"! Almost as bad is one of the quoted 'tests' of this theory: wildebeest do not defend territories because it would not be adaptive for them to do so. It is a great pity that Barash gives readers the impression that "sociobiologic theory" (which I call natural selection) makes only tautologous or trivial and uninteresting predictions, because evolu-

tionary theory can be used to make highly quantitative and often counter-intuitive predictions just like any proper hypothesis.

My third criticism is that Barash, in his effort to make the book simple, often stops short of the point where he could convey some real understanding of the issues involved. Let me give a few examples. The discussion of costs and benefits of ritualised fighting (p.233) simply misses the point because it does not make clear the fact that the benefit to an individual derived from any particular strategy depends on what everyone else does. The payoffs are frequency dependent, so the problem is to find an evolutionary stable strategy. The same line of reasoning should have been applied to the review of mating systems (p.168 *et seq.*). In summarising the idea of sexual selection, Barash presents one hypothesis (the "handicap principle") without pointing out any of its known pitfalls, and fails to make a clear statement of the most widely accepted idea (Fisher's theory). The important work of Trivers and Hare on eusocial insects is incorrectly reported in a single sentence on p.84; the cost of sex is incorrectly explained on p.139; and although Barash asserts on p.119 that "gregariousness in shorebirds represents a unique and optimal compromise between conflicting demands of predation . . . and . . . foraging interference", the reference he cites has no information on whether or not spacing is optimal.

These points, and many other similar ones, are not too difficult to explain to first-year undergraduates (see *The Selfish Gene* by Richard Dawkins, Oxford University, 1976), and I feel that it is absolutely essential to get things exactly right if one is to convince students that evolutionary biology is more than a hand-waving exercise.

A final point about presentation. The text is well illustrated with good graphs, but inexplicably the photographs often have little to do with the text. A description of distraction displays in the Killdeer is accompanied by a photograph of two cranes, a pair of male Topis serves to illustrate territorial behaviour in the Wildebeest, and plate 3.3, a bizarre study of grey blobs, defies analysis.

Hückel molecular orbital model

The HMO Model and its Application. Vol. 2: Problems with Solutions. Vol. 3: Tables of Hückel Molecular Orbitals. By E. Heilbronner and H. Bock. Translated by W. Martin and J. Anthony Rackstraw. Pp. viii+449 and viii+190. (Wiley-Interscience: London and New York; Verlag Chemie GmbH: Weinheim, 1976.) £15 and £9; \$33 and \$18.

THESE volumes complete Heilbronner and Bock's handbook on the Hückel molecular orbital model. Volume 1 set out the basic theory and techniques, and contained numerous problems; Volume 2, which is almost as long, contains only the solutions to those problems. Anyone who works through all the problems would acquire a very extensive knowledge of Hückel theory. I suspect, however, that this knowledge would be deficient in being rather mechanical, superficial and uncritical. It is typical, for example, that although the main text provides an adequate

general derivation of the pairing theorem, the associated problem requires the reader to prove that a crude approximate formula for Hückel energies also satisfies the theorem—a result of far less power and significance. Again, the authors provide a mechanical procedure for factorising a Hückel determinant with the help of the molecular symmetry. Not only is it mechanical; it is also unnecessarily laborious, since it involves a lengthy series of operations on the entire secular determinant. Not only that; it doesn't even work where there are degeneracies (try it for cyclopropenyl). Setting up the determinant directly in terms of symmetry-adapted functions is easier, more general, and more illuminating.

Hückel theory is well known to be a very poor approximation for many purposes. The authors point out some of its failings, but do not indicate how they may be overcome, even by providing a suitable reference. Examples are the failure to predict negative spin populations, and the false degeneracy of the second excited state of alternant hydrocarbons. These are both due to the failure of Hückel theory to take account of electron repulsion; however, in both cases a simple correction can

be made to improve the Hückel result.

The third volume contains tables of Hückel molecular orbital coefficients and derived quantities such as bond orders and atom-atom polarisabilities. It covers chains (up to 10 atoms), rings (up to 18 atoms), an assortment of alternant and non-alternant molecules with up to three rings, and the partial π systems obtained by removing one carbon atom from naphthalene, anthracene, phenanthrene, azulene and biphenylene. It is intended partly as an adjunct to the problems, many of which refer to the data in the tables; however, it is also more generally useful. On the other hand, when writing a Hückel molecular orbital programme is a straightforward undergraduate exercise it cannot be said that the need for such tables is very great.

In summary, the work cannot be regarded as a definitive treatise on Hückel theory: it omits too much. As an introduction it is reasonably thorough, although even here there are some omissions. A useful but not indispensable book. **A. J. Stone**

A. J. Stone is an Assistant Director of Research in Theoretical Chemistry at the University of Cambridge, UK.

Plasma in gas

Plasma Phenomena in Gas Discharges. By R. N. Franklin. (Oxford Engineering Science Series.) Pp. ix+249. (Clarendon; Oxford: Oxford University: London, 1976.) £15.

LECTURE courses spawn books as readily as the proverbial salmon spawning eggs. Unfortunately graduate courses and the books they gestate too frequently limit themselves to the particular interests of the lecturer. This would seem to be the rationale behind this scholarly but narrow book by Raoul N. Franklin.

The book is largely concerned with analysing the positive column and illustrating the diversity of plasma phenomena which can occur therein. Though these small scale, low current, experiments are of great importance in the historical development of plasma physics, they nevertheless represent a very small area in what is now a much wider experimental field.

In the first half of the book detailed solutions of radial equilibrium, of space-charge effects at walls and electrodes and of the influence of a magnetic field in a positive column are presented. The second half of the book rests a little uneasily on the first part and aims to describe the variety

of plasma phenomena that can be observed in gas discharges. It is largely, however, a catalogue of linear plasma waves, including electron plasma waves, ion waves, ionization waves, magnetosonic and 'whistler' waves and drift waves. As a description of wave phenomena in plasmas, it is a useful and reasonably comprehensive compendium, though at this level it must be compared with many excellent books on waves in plasmas. I would have been happier with more physical insight, discussion and interpretation of the equations used and results obtained, as opposed to the *ad hoc* writing down of equations, linearisation and solution of the resultant dispersion relations. As a wide catalogue and a clear analysis of waves in plasma it is useful. A helpful feature is the inclusion of comparisons with experiment whenever possible and a wide range of references to experimental work.

Though the editing can be faulted and the production is dull, the book is scholarly and precise. It is certainly a useful text for those working directly in gas discharges but of less value to the wider student of plasma physics.

Recent scientific and technical books

Mathematics

- BIERMAN, Gerald J. Factorization Methods for Discrete Sequential Estimation. (Mathematics in Science and Engineering: a Series of Monographs and Textbooks, Vol. 128.) ISBN-0-12-097350-2. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) \$19; £13.50.
- COHN, P. M. Skew Field Constructions. (London Mathematical Society Lecture Note Series, No. 27.) Pp.xii+253. ISBN-0-521-21497-1. (Cambridge, London and New York: Cambridge University Press, 1977.) £7.50.
- HATTON, M. D. Mathematical Analysis. Pp. 242. ISBN-0-340-20825-2. (London, Sydney, Auckland and Toronto: Hodder and Stoughton, 1977.) Boards £4.75; Paperback £2.45.
- HIGGINS, J. R. Completeness and Basis Properties of Sets of Special Functions. (Cambridge Tracts in Mathematics, Vol. 72.) Pp.x+134. ISBN-0-521-21376-2. (Cambridge, London and New York: Cambridge University Press, 1977.) £9.80 net.
- JAMES/JAMES. Mathematics Dictionary. Fourth edition. Pp.vii+509. ISBN-0-442-24091-0. (New York and London: Van Nostrand Reinhold Company, 1976.) £13.65.
- JEFFREYS, Sir Harold, and SWIRLES, Bertha (Lady Jeffreys) (edited by). Collected Papers of Sir Harold Jeffreys on Geophysics and Other Sciences. Vol. 6: Mathematics, Probability and Miscellaneous Other Sciences. Pp.xviii+622. ISBN-0-677-03220-X. (London, Paris and New York: Gordon and Breach Science Publishers, 1977.) £35.30.
- KUSSMAUL, A. U. Stochastic Integration and Generalized Martingales. (Research Notes in Mathematics, Vol. 11.) Pp. 163. ISBN-0-273-01030-1. (London, San Francisco and Melbourne: Pitman Publishing, Ltd., 1977.) £7.
- MURA, Roberta Botto, and RHEMUTULLA, Akbar. Orderable Groups. (Lecture Notes in Pure and Applied Mathematics.) Pp. iv+169. ISBN-0-8247-6579-6. (New York and Basel: Marcel Dekker, Inc., 1977.) \$Fr. 66.
- TRUESDELL, C. A. First Course in Rational Continuum Mechanics. Vol. 1: General Concepts. (Pure and Applied Mathematics: a Series of Monographs and Textbooks.) Pp.xiii+280. ISBN-0-12-701301-6. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) \$23; £16.35.
- TSICHRITZIS, D. C., and LOCHOVSKY, F. H. Data Base Management Systems. (Computer Science and Applied Mathematics: a Series of Monographs and Textbooks.) Pp.xvi+388. ISBN-0-12-701740-2. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) \$16.95; £12.05.
- TSOKOS, Chris P., and SHIMI, I. N. (edited by). The Theory and Applications of Reliability. With Emphasis on Bayesian and Nonparametric Methods. Vol. 1: Pp.xvi+549. ISBN-0-12-702101-9 (V.1) \$25; £17.75. Vol. 2: Pp. xvi+582. ISBN-0-12-702102-7 (V.2) \$26; £18.45. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.)
- WANG, Hwai-chuan. Homogeneous Banach Algebras. (Lecture Notes in Pure and Applied Mathematics.) Pp. vii+204. ISBN-0-8247-6588-5. (New York and Basel: Marcel Dekker, Inc., 1977.) \$Fr. 66.
- WHITEMAN, J. R. (edited by). The Mathematics of Finite Elements and Applications II. MAFFELAP 1975. (Proceedings of the Brunel University Conference of the Institute of Mathematics and Its Applications, held in April, 1975.) Pp. xiii+573. ISBN-0-12-747252-5. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) £21; \$41.

Astronomy

- SMITH, F. G. Pulsars. (Cambridge Monographs on Physics.) Pp. xii+239. ISBN-0-521-21241-3. (Cambridge, London and New York: Cambridge University Press, 1977.) £9.50.

Physics

- BLOEMBERGEN, N. (edited by). Nonlinear Spectroscopy. (Proceedings of the International School of Physics (Enrico Fermi), Course LXIV, Varenna on Lake Como, 30 June-12 July 1975. Italian Physical Society.) Pp.xii+455. ISBN-0-7204-0568-8. (Amsterdam, New York and Oxford: North-Holland Publishing Company, 1977.) Dfl. 127.50; \$61.25.
- COLLINS, P. D. B. An Introduction to Regge Theory and High Energy Physics. (Cambridge Monographs on Mathematical Physics, 4.) Pp.xiii+445. ISBN-0-521-21245-6. (Cambridge, London and New York: Cambridge University Press, 1977.) £29.
- EISBERG, Robert M. Applied Mathematical Physics with Programmable Pocket Calculators. Pp.xii+176. ISBN-0-07-019109-3. (New York and London: McGraw-Hill Book Company, 1976.) £5.20.
- HOLT, Maurice. Numerical Methods in Fluid Dynamics. (Springer Series in Computational Physics.) Pp.viii+253. ISBN-3-540-07907-6. (Berlin and New York: Springer-Verlag, 1977.) DM 72; \$31.70.
- IBACH, H. (edited by). Electron Spectroscopy for Surface Analysis. (Topics in Current Physics Vol. 4.) Pp.xi+255. ISBN-3-540-08078-3. (Berlin and New York: Springer-Verlag, 1977.) DM 64; \$28.20.
- KOESTER, L., and STEYERL, A. (contributions by). Neutron Physics. (Springer Tracts in Modern Physics/Ergebnisse der Exakten Naturwissenschaften, Vol. 80.) Pp. vii+135. ISBN-3-540-08022-8. (Berlin and New York: Springer-Verlag, 1977.) DM 64; \$28.20.
- MIGDAL, A. B. Qualitative Methods in Quantum Theory. Translated from the Russian edition by Anthony J. Leggett. (Frontiers in Physics: a Lecture Note and Reprint Series.) Pp.xiii+435. ISBN-0-8053-7064-1. (Reading, Mass. and London: W. A. Benjamin, Inc., 1977.) \$21.50.
- MORRISON, S. Roy. The Chemical Physics of Surfaces. Pp. xvii+415. ISBN-0-306-30960-2. (New York and London: Plenum Press, 1977.) \$47.40.
- SHEN, Y.-R. (edited by). Nonlinear Infrared Generation. (Topics in Applied Physics, Vol. 16.) Pp.xi+279. ISBN-3-540-07945-9. (Berlin and New York: Springer-Verlag, 1977.) DM 88; \$38.80.
- SOMOGYI, I. Kosa (edited by). Amorphous Semiconductors '76. (Proceedings of the International Conference, Balatonfüred, Hungary, 20-25 September, 1976.) Pp. 565. ISBN-963-05-1272-6. (Budapest: Akadémiai Kiadó, 1977.) £19.20.
- STUMP, D. R., and WEINGARTEN, D. H. (edited by). Quark Confinement and Field Theory. (Proceedings of a Conference at The University of Rochester, Rochester, New York, June 14-18, 1976.) Pp.vii+253. ISBN-0-471-02721-9. (New York and London: Wiley-Interscience, John Wiley and Sons, 1977.) £18.70; \$31.70.
- TSYTOVICH, V. N. Theory of Turbulent Plasma. Translated from Russian by David L. Burdick. (Studies in Soviet Science: Physical Sciences.) Pp.xvii+535. ISBN-0-306-10894-1. (New York and London: Consultants Bureau, a Division of Plenum Publishing Corporation, 1977.) \$54.
- WATTS, R. K. Point Defects in Crystals. Pp.xi+312. ISBN-0-471-92280-3. (New York and London: Wiley-Interscience, John Wiley and Sons, 1977.) \$27.90; £16.50.

Chemistry

- AEMND, John R. Introductory Chemistry: Models and Basic Concepts. Pp. xvi+470. ISBN-0-471-02533-X. (New York and London: John Wiley and Sons, 1977.) \$20; £12.

- AKERS, R. J. (edited by). Foams. (Proceedings of a Symposium organised by the Society of Chemical Industry, Colloid and Surface Chemistry Group, and held at Brunel University, September 8-10, 1975.) Pp.x+301. ISBN-0-12-047350-X. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) £12; \$23.50.
- ARMAREGO, W. L. F. Stereochemistry of Heterocyclic Compounds. Part I: Nitrogen Heterocycles. (General Heterocyclic Chemistry Series.) Pp.xvi+433. ISBN-0-471-01892-9. (New York and London: Wiley-Interscience, John Wiley and Sons, 1977.) \$45; £27.
- BACON, G. E. Neutron Scattering in Chemistry. Pp.186. ISBN-0-408-70800-X. (London and Boston, Mass.: Butterworth and Co. (Publishers), Ltd., 1977.) £12.50.
- BILLINGHAM, N. C. Molar Mass Measurements in Polymer Science. Pp.254. ISBN-0-85038-320-X. (London: Kogan Page, 116A Pentonville Road, N1, 1977.) £13.50 net.
